The Incremental Information Content of Tone and Sentiment in Management Discussion and Analysis

Abstract

This study explores whether the Management Discussion and Analysis (MD&A) section of Form 10-Q and 10-K has incremental information content beyond financial measures such as earnings surprises, accruals and operating cash flows (OCF). It uses a well-established classification scheme of words into positive and negative categories to measure the tone and sentiment in a specific MD&A section as compared to those of the prior four filings. Our results indicate that short window market reactions around the SEC filing are significantly associated with the tone of the MD&A section, even after controlling for accruals, OCF and earnings surprises. We also show that the tone of the MD&A section adds significantly to portfolio drift returns in the window of two days after the SEC filing date through one day after the subsequent quarter’s preliminary earnings announcement, beyond financial information conveyed by accruals, OCF and earnings surprises.
The Incremental Information Content of Tone and Sentiment in Management Discussion and Analysis

There is a substantial body of literature in financial economics and accounting that examines the value relevance and information content of quantitative factors in the pricing of stocks. While economic and statistical modeling has become more sophisticated over the years, the somewhat disconcerting conclusion that seems to have emerged is that these quantitative factors inadequately explain movement of stock prices. Persuasive evidence of this is provided by Shiller (1981), Roll (1988), and Cutler et al. (1989), and others in the finance literature, who demonstrate that stock prices do not respond to change in quantitative measures of firm fundamentals as would be expected from models incorporating only quantitative variables of firm performance. In the accounting literature, Lev and Thiagarajan (1993), and Amir and Lev (1996), are two examples of research that have shown the inadequacy of conventional quantitative financial measures in pricing a firm’s stock. All in all, there is a growing realization that to develop a “good” stock pricing model, one has to incorporate not only the conventional quantitative measures of firm performance, but also include non-conventional measures such as potential market share (Amir and Lev, 1996), and even verbal, non-quantitative, difficult to quantify, kinds of measures.

This is not totally surprising from a theoretical perspective. After all, stock prices are set by investors who, by definition, compute prices as the discounted present value of future cash payoffs conditional on the current information set available to them. It seems natural then to expect that the investor information set should include not only quantifiable information, but also non-quantifiable, verbal information, such as news
articles. Indeed, Tetlock (2007) examines whether the general negative or pessimistic flavor of a particular daily news column from the *Wall Street Journal* (WSJ) (titled “Abreast of the Market”) covering the stock market activity on the previous day influences prices of market indices of stocks. The depth of article pessimism is defined as the proportion of negative words used in this column. After controlling for other variables, he finds that the depth of pessimism in this column does put a significant downward (temporary) pressure on prices of the stock indices.\(^1\)

Tetlock et al. (2008) further examines the ability of negative words used in *WSJ* and the *Dow Jones News Service* (DJNS) columns about S&P 500 firms to predict future earnings and stock returns on the day after the publication of these news articles. They find that the proportion of negative words in these news stories (especially, negative words about a firm’s fundamentals) do provide information about future earnings even after controlling for other factors. They show that the higher the proportion of negative words (especially, negative words pertaining to firm fundamentals), the larger are the negative shocks to future earnings. In addition, they provide persuasive evidence that potential profits could be made by trading on negative words from *DJNS*, a timely news service (but not from the one day old information published in the WSJ).\(^2\)

The two Tetlock papers remain among the first of their kind to assess the predictive content of non-quantitative verbal information and are the main motivators of

---

\(^1\) Following the initial impact on stock prices due to the media pessimism factor, the prices of indexes of smaller stocks reverse more slowly than those of large firms. In addition, he also provide persuasive evidence to show that pessimism is not a proxy for risk. As an additional feature, they also find that unusually high or low pessimism among investors leads to temporarily high trading volume.

\(^2\) The authors acknowledge that these profits could be wiped out by transactions costs from high frequency trading.
our work. By focusing on news stories in media, their work is more concerned with pessimism expressed by outsiders (media-persons), except for press releases issued by the firms. While there is no doubt that these papers make a strong case for the predictive value of pessimism expressed by outsiders on stock prices and future earnings, they may not completely capture the views of managers (or insiders), when those are required to express their views in Securities and Exchange (SEC) filings. It can be argued that if managers are better informed than outsiders, and assuming that they truthfully report their views (under SEC scrutiny and penalty of litigation), then their statements may have higher predictive ability than outsiders’ reports.

Our study investigates the information content and value relevance of the “tone” and “sentiment” conveyed through Management Discussion and Analysis (MD&A) disclosures for a large sample of firms. By “tone” and “sentiment”, we mean the pessimism or optimism of the information embedded in non-quantifiable verbal disclosures by managers in the MD&A section of firms’ periodic SEC filings. Specifically, we are interested in studying if the tone and sentiment expressed verbally in the MD&A contains any additional information about stock prices beyond what is captured by preliminary earnings surprises, accruals, and operating cash flows (OCF). The latter three variables are known to be informative about the future stock performance.

---

3 We note that Abrahamson and Amir (1996) perform a content analysis of over 1,300 President’s Letters to shareholders for firms trading in the NYSE and written between 1986 and 1988. They show that while the relative “negative” content of the letter (measured by a proprietary computer program) reflects past performance of a firm and is priced by the market, it can also (weakly) predict future firm stock performance.

4 Kothari and Short (2003) is probably the first paper to recognize this and examine the information content of MD&A disclosures in addition to the information content of analysts forecasts and media reports using a methodology similar to Tetlock (2007) and Tetlock et al. (2008). However, they focus on the effects of the MD&A’s sentiment on the firm’s cost of capital and risk (stock price volatility), not on their ability to predict future stock prices and earnings.
of the firm. Consequently, the usefulness of the tone and sentiment in the MD&A reports can only be judged by what it contributes incrementally to these three quantitative measures.

We find that the tone and sentiment in MD&A sections of the SEC filings do, in fact, contain information orthogonal to accruals, OCF, and earnings surprises. We show by regression analysis and by explicit construction of buy and hold type portfolio strategies, that the optimism, pessimism, and especially the differential optimistic tone and sentiment measure, yield excess average stock returns over the short window following the filing of the MD&As, but also that returns continue to drift for longer periods that extend until after the subsequent quarter’s preliminary earnings announcement. The implication is that the non-quantitative tone and sentiment expressed in MD&As can be potentially exploited to earn significant excess returns over and above those associated with well known trading strategies based on accruals, OCF, and earnings surprises alone.

Our results contribute to the information content and value relevance of SEC filings and mandated disclosures. Specifically, our paper contributes to the value relevance of disclosures in the MD&A statements. To the best of our knowledge, we are the first to measure and show that the tone and sentiment expressed by management through non-quantifiable words in MD&A are value relevant, informative, and can predict future stock prices beyond well-known measures of company performance. Our findings are of interest to academics who are interested in such issues as market efficiency and how well public information is captured in security prices. The results of our study are relevant to policy-makers because it shows the incremental valuation
relevance of required non-quantitative information. The results are of interest for practitioners as well, since the tone and sentiment in SEC filings (which are filed regularly) can be used to improve portfolio performance beyond quantitative variables, although they may be more costly to implement.\(^5\)

The rest of the paper is organized as follows: The next section reviews the relevant literature and motivates our research hypotheses. Section 3 describes the sample, defines and describes the variables used in our paper. Section 4 presents our results and Section 5 concludes our paper.

2. Prior Research and Research Questions

2.1 Prior Research

Broadly speaking, there are two kinds of research relating to the valuation of corporate disclosures in the accounting literature, namely, the voluminous body of work that has examined the value relevance (or information content) of quantitative financial disclosures,\(^6\) and the relatively smaller set of research papers that have studied the valuation of non-financial disclosures. Within studies of value relevance of non-financial data there are two major sub-groups; those that focus on quantifiable data and those that examine non-quantifiable verbal expositions that elaborate and explain quantitative disclosures. Our research examines the information content of narratives from MD&A and so is related to the latter stream of research. However, in examining the incremental value relevance of MD&A disclosures, we control for the value relevance of financial variables that have been extensively documented by prior studies.

---

\(^5\) The set-up costs required for analyzing the tone and sentiment of qualitative disclosure may favor professional investors.

\(^6\) We refer the interested reader to the book by Beaver (2003) for a discussion and analysis of the value relevance of financial disclosures.
We cite two papers that examine the incremental information content of quantifiable non-financial information.\footnote{These papers provide citations for the interested reader.} Using a large sample of firms from 1974-1988, Lev and Thiagarajan (1993) show that certain non-audited but quantifiable information, such as order backlogs and the strength of their labor force, provide information for valuation over and beyond the traditional financial accounting information. Amir and Lev (1996) further build on this theme by studying the value relevance of financial and non-financial data for a sample of wireless communication firms and find that financial data alone show very little value relevance, but if combined with quantifiable non-financial data (specifically, proxies for potential customers) the value relevance of these financial variables are considerably enhanced.

Some of the early research relating to MD&A is mostly descriptive in its content. Bagby et al. (1988) provide a historical review of MD&A and the social usefulness of non-quantitative disclosures within a broader framework of federally mandated disclosures using a critical examination of legal cases relating to mandated disclosures. Dieter and Sandefur (1989) outline the MD&A requirements mandated by the SEC and suggest guidelines on drafting a MD&A that would satisfy these regulations in form and substance.

Shroeder and Gibson (1990) is among the earliest papers to try and quantify the readability quotient of the exposition in the MD&A and also the President’s letter. Borrowing techniques from the Psychology literature, they construct the so-called Flesch Index scores (a presumably reliable subjective measure of reading ease) using a standard formula based on the word length and sentence length, and by also examining the general
flavor of the language used (active versus passive voice in sentence constructions), they conclude that MD&A statements in general are less than readable.

One of the earliest papers in the accounting literature that use linguistic techniques to analyze narrative disclosures is Frazier et al. (1984). Using a computer program called WORDS to identify the most important words (or factors) that could be reasonably interpreted as positive or negative narrative themes for a sample of 74 annual reports of firms in 1978 they show that there are no significant differences in managerial narratives across the ownership structure of these firms. They also provide persuasive evidence to support their hypothesis that the positive and negative factors (and the associated themes) can predict the cumulative abnormal annual returns for the next year (1979).8

Pava and Epstein study the MD&A disclosures of 25 randomly selected firms during 1989 and find that while the disclosures provided adequate details of historical events, they did a better job of predicting firm specific, industry specific, and economy specific good news than predicting bad news for 1990. They conclude that managers may be withholding disclosures related to bad news. While these studies are related to our work, their samples are small and limited to specific early years prior to revised SEC’s guidelines on MD&A and the availability of EDGAR.

In 1989, the SEC issued guidelines to clarify what was expected in the MD&A disclosures in an attempt to make the MD&A more informative. Hooks and Moon (1993) attempt to measure the differences between actual and expected frequency of MD&A disclosures across a spectrum of disclosures that they classify as mandated to those that are classified as voluntary, and show that these differences have decreased for certain

---

8 The paper also discusses other applications of WORDS in finance and accounting.
items after the SEC MD&A guideline release in 1989, indicating firms provide more disclosure in their MD&A post 1989.

Bryan (1997) examines if the specific accounting related narratives from MD&A have incremental information content beyond quantitative financial statement information regarding future financial variables such as the directions of changes in future sales, in future earnings per share, future operating cash flows, and future capital expenditures. Using a sample of MD&A disclosures by 250 firms in 1990 (a year after clearer guidelines were issued by the SEC), he finds that there is a strong association between MD&A disclosures and the direction of changes in the aforementioned future financial variables three years into the future. In addition, he demonstrates that MD&A disclosures, especially, the disclosure relating to capital expenditures, are significantly associated with financial analyst forecasts and stock returns around the release date of MD&As. Bryan’s paper differs from our work in that we are interested in the predictive ability of the overall sentiment of the MD&A rather than the content of the individual disclosures. He does not examine if abnormal stock returns can be earned or study the issue of post announcement drift in stock prices. More importantly, while the sentiment factor is shown to be distinct from other risk related factors (Tetlock, 2007, Tetlock et al., 2006, Botosan9, 1997), the individual MD&A disclosures may be highly correlated and related to the same risk factors. Further, the content analysis by Bryan is subjective as opposed to theoretical sound sentiment index used here and by Tetlock (2007) and Tetlock et al. (2006). Finally, our sample size is much larger and is drawn from years when the legal and disclosure environments are substantially different.

9 Botosan (1997) examines a sample of 122 manufacturing firms’ annual reports for 1990 including the MD&A, and concludes that the quality of financial disclosures is not associated with the firms’ cost of capital. It is to be noted that the quality measure developed in this paper is somewhat subjective.
There are few papers that examine the relationship between MD&A disclosures and analyst forecasts. One such paper is by Barron and Kile (1999). Using a large sample of firms drawn from 1987-1989 MD&A disclosures of 26 different industries, and after controlling for quantitative financial factors, they show a strong association between the accuracy of analysts’ forecasts and the quality of MD&A disclosures (as measured by scores assigned by personnel at the Securities Exchange Commission), especially disclosures relating to capital expenditures. Clarkson et al. (1997) document that MD&A disclosures are found to be useful to sell-side analysts who are members of the Toronto Society of Financial Analysts (TSFA) based on 33 responses to questionnaires. In addition, using a sample of 55 firms on the Toronto Stock Exchange (TSE) 100 firms between 1991 and 1992, they show that the levels and the changes in the quality of various sub-sections of the MD&A disclosures (where the quality of disclosures is a score provided by the members of TSFA) are generally determined by expected firm performance, financing activities (mainly increased equity financing), firm size, independent press reports, and major firm related events.

Cole and Jones (2004) use MD&A disclosures from a sample of 150 firms for the period 1996-1999 from the retail industry to show that certain types of quantifiable disclosures, (namely sales growth, store openings and closings and capital expenditures), can predict future profitability, and are associated with contemporaneous stock returns. Sun (2007) examines the MD&A disclosures explaining inventory increases between 1998 and 2002 for 568 manufacturing firms and shows that favorable explanations are associated with future profitability and sales growth, and firms in growth industries and competitive industries tend to disclose more.
Kothari and Short (2003) is perhaps the first work to have used the General Inquirer program (which we use in this study) to assess the content or sentiment expressed in MD&A disclosures. They extend the work of Botosan (1997) by studying the effect of the positive and negative sentiments expressed in MD&A, analyst reports, and the financial press between 1996 and 2001 on the cost of capital and risk (stock price volatility) for a sample of 887 firms from 4 industries (Technology, Telecommunications, Pharmaceutical, and Financial). They find that aggregated (across all three sources) positive (favorable) disclosures decreased the cost of capital and the stock return volatility of the firm, while negative (unfavorable) disclosures had the opposite effects. However, when disclosures are analyzed by specific sources, they find that positive sentiments expressed in corporate MD&As do not have an effect on the cost of capital, while negative sentiments significantly increase it. They attribute this to skepticism on the part of investors regarding positive disclosures (that is they are viewed more as self-serving), but find negative sentiments credible because management would not normally reveal bad news. Disclosures relating to analysts’ sentiments seem to have no effect on the cost capital, and this is attributed to the lack of credibility. They attribute this to the fact that analysts are seen to be reporting their sentiments after the market has already absorbed them. Finally, they find that positive media (press etc.) stories and disclosures seem to decrease the cost of capital and negative disclosures increase it.\footnote{This supports the findings of Tetlock (2007) that shows similar results for market index (Dow Jones Index), that is when the media reports are pessimistic, the stock index price drops and market volatility increases.}

As mentioned before, the two papers that are closest in spirit to ours are by Tetlock (2007) and Tetlock et al. (2008). They do not focus on pessimism and predictive content of MD&As but on news columns and news releases. Tetlock (2007) uses a
computer program known as the General Inquirer to assess the negative quotient of the *Wall Street Journal* daily column called “Abreast of the Market” from 1984 to 1999, and finds that pessimistic articles generally put temporary downward pressures on market prices (*Dow Jones* stock index) and increase trading volume in the New York Stock Exchange (*NYSE*). The increased volume of trade is consistent with the microstructure theory that predicts high absolute values of pessimism should lead to a group of liquidity traders trading more, and refutes the suggestion that the pessimism factor is a proxy for transaction costs (Tetlock, 2007). It is important to note that Tetlock (2007) finds that higher pessimism leads to higher volatility (risk) for the *Dow Jones* portfolio of stocks. This goes against the intuition that higher pessimism should lead to lower returns, or equivalently, lower risk, suggesting that the pessimism factor captured by negative words may be distinct from risk. This is further corroborated by the fact that the effects of pessimism seem to be temporary and future stock returns reverse. Continuing this line of research, Tetlock et al. (2008) examine the ability of media pessimism measured by the proportion of negative words in the real time stories news from *DJNS* and daily news stories in the *WSJ* between 1984 and 2004 relating to S&P 500 firms to predict future earnings and returns. They show that the proportion of negative words (especially those relating to firm fundamentals) in these news releases do convey information about firm future earnings. They also find that the proportion of negative words in the timely news releases from *DJNS* lead to lower stock returns the following trading day and this trend persists over the next 10 days. These results remain robust even after controlling for other

---

11 If the pessimism factor were a proxy for transactions costs, then higher levels of pessimism should lead to lower volumes of trading on the following periods (see Tetlock, 2007)

12 This reversal seems to be slower for small firms’ stocks relative to stocks of big firms when the tests are run on stocks other than those in the Dow Jones Index.
sources like analysts’ forecasts, past stock returns, and historical accounting data. The authors show that a simple trading strategy of constructing portfolios that short stocks of firms with negative words in the DJNS news stories the previous day and long on the stocks with relatively few negatively worded stories produces significant abnormal returns (excluding transactions costs).

In related research, Abrahamson and Amir ((1996) perform a content analysis of over 1,300 President’s Letters to shareholders for NYSE firms and written between 1986 and 1988. They show that relative negative content of the letter (measured by a proprietary computer program) is strongly negatively associated with past and future performance as measured by accounting variables, strongly negatively associated with past and contemporaneous (yearly) returns, and weakly negatively associated with future returns.

2.2 Research Questions

Investors’ in stocks may be able to exploit disclosures of accruals, OCF, and earnings surprises (usually, constructed as a standardized measure of an abnormal earnings metric or SUE) immediately (short window) following these disclosures, and over the longer term future as well. Of the three, the influence of earnings surprises on stock prices is perhaps the oldest and best documented phenomenon. It has been repeatedly shown that positive (negative) earnings surprises exert immediate upward (downward) pressure on prices and surprisingly, this trend continues to persist for a long time after the initial disclosure (the post-announcement drift anomaly). Investors can exploit this anomaly by holding differential positions of stocks with extreme positive and
In addition to earnings surprises, the accounting and finance literature has also documented the information relevance of accruals and net Operating Cash Flow (OCF). Sloan (1996) shows that firms with extremely low annual accruals outperform firms with extremely high accruals. His study was corroborated by many subsequent studies with annual accruals and recently by Livnat and Santicchia (2005) with quarterly accruals. Desai et al. (2004) question whether accruals are a superior signal to OCF, which has been documented to be valuation relevant by Lakonishok et al. (1994). The question of whether accruals are incrementally informative beyond OCF has also been addressed by Cheng and Thomas (2006) and Barone and Maglike (2006) using annual data and Livnat and Lopez-Espinosa (2007) using quarterly data. In addition, Collins and Hribar (2000) and more recently Battalio et al (2007) show that earnings surprises and accruals are two distinct anomalies and using each yields incremental abnormal returns beyond the other.

Our research examines if the tone and sentiment expressed in MD&A disclosures are associated with contemporaneous and future abnormal returns (short window following the MD&A disclosure and the post announcement long term drift) over and above what is associated with preliminary earnings reports (SUE), accruals, and OCF. Following Tetlock (2007) and Tetlock et al. (2008), we define a pessimistic tone and sentiment as the proportion of negative words among all words in the MD&A. The larger this proportion, the more pessimistic is the tone and sentiment. We also define an optimistic metric by constructing a similar metric with positive words, and further construct a differential optimistic tone and sentiment measure by taking the difference of
the positive and negative words divided by the sum of positive and negative words in the MD&A.

Our control variables are SUE, accruals and OCF, which we measure as in the prior literature. When there are no analyst forecasts for the quarter, SUE is calculated from the *Compustat* quarterly database as preliminary income (Quarterly item 8) for quarter t minus as-first-reported income for quarter t-4, scaled by the market value of equity at the end of quarter t-1. When there is at least one analyst forecast for quarter t on IBES, the SUE is calculated as the actual *I/B/E/S* EPS minus the mean analyst forecast during the 90-day period before the disclosure of earnings, scaled by the price per share at the end of the quarter. Accruals (OCF) /Average Assets equals income before extraordinary items and discontinued operations minus cash from operations (OCF), scaled by average total assets during the quarter.

We show that there are significant incremental abnormal returns around the filing date and for the long term drift both by constructing buy and hold type portfolio strategies\(^\text{13}\) that incorporate the tone and sentiment factor in addition to the SUE, accruals, and OCF, and running quarterly regressions as in Fama-Macbeth (1973).

### 3. Data and Sample Selection

#### 3.1 The Preliminary and Un-restated Compustat Quarterly Data

Data entry into the Compustat databases has been performed in a fairly structured manner over the years. When a firm releases its preliminary earnings announcement,

\(^{13}\) Short window abnormal returns surrounding MD&A disclosures are defined as Buy and hold return on a stock minus the average return on a matched size-B/M portfolio over the days [-1,+1], where day 0 is the SEC filing date. The excess drift return for the longer term is the buy and hold return on a stock minus the average return on a matched size-B/M portfolio from two days after the SEC filing date through one day after the subsequent quarter’s preliminary earnings announcement.
Compustat takes as many line items as possible from the preliminary announcement and enters them into the quarterly database within 2-3 days. The preliminary data in the database are denoted by an update code of 2, until the firm files its Form 10-Q (10-K) with the SEC or releases it to the public, at which point Compustat updates all available information and uses an update code of 3. Unlike the Compustat Annual database, which is maintained as originally reported by the firm (except for restated items), the Compustat Quarterly database is further updated when a firm restates its previously reported quarterly results. For example, if a firm engages in mergers, acquisitions, or divestitures at a particular quarter and restates previously reported quarterly data to reflect these events, Compustat inserts the restated data into the database instead of the previously reported numbers. Similarly, when the annual audit is performed and the firm is required to restate its previously reported quarterly results by its auditor as part of the disclosure contained in Form 10-K, Compustat updates the quarterly database to reflect these restated data.

Charter Oak Investment Systems, Inc. (Charter Oak) has collected the weekly original CD-Rom that Compustat sent to its PC clients, which always contained updated data as of that week. From these weekly updates, Charter Oak has constructed a database that contains three numbers for each firm for each Compustat line item in each quarter. The first number is the preliminary earnings announcement that Compustat inserted into the database when it bore the update code of 2. The second number is the “As First Reported” (AFR) figure when Compustat first changed the update code to 3 for that firm-quarter. The third number is the number that exists in the current version of Compustat, which is what most investors use. The Charter Oak database allows us to use the first-
reported information in the SEC filing, so that quarterly earnings, cash flows and accruals
correspond to those reported originally by the firms, which were also available to market
participants at the time of the SEC filing. Using the restated Compustat Quarterly
database may induce a hindsight bias into back-tests, since we may have used restated
earnings, cash flows or accruals that were not known to market participants on the SEC
filing dates.

3.2 Sample Selection

To reduce the potential bias that may occur by using a sample of quarterly
information that became available through SEC filings before the SEC’s EDGAR
database and afterwards, this study concentrates on SEC filings that are available through
the EDGAR database from the fourth quarter of 1995 through the second quarter of 2006.
Conceptually, information in SEC filings on the SEC EDGAR database is likely available
to users at a very low cost immediately after the filing date indicated in the EDGAR
database. Prior to EDGAR, information about SEC filings were available from the
companies directly or from the SEC library with a lag (see, e.g., Easton and Zmijewski,
1993). The problem with the SEC EDGAR database is that it identifies firms according to
CIK codes, which are not well-mapped into other databases used in practice and academe
such as Compustat or CRSP.

The Standard & Poors’s (S&P) Filing Dates database seeks to fill this void14. It
contains a match between all companies on the Compustat database (identified by
GVKEY) with the CIK identifiers on the SEC EDGAR database15. The S&P Filing Dates
database matches all Compustat firms (by GVKEY) to CIK codes on the SEC EDGAR

---

14 The database is available through WRDS or directly from S&P.
15 The database includes all GVKEY’s where the market value of the firm’s equity at quarter-end exceeded
$1 million.
database as they were known on the Compustat database at the time through the Charter Oak database. Thus, it is useful in constructing a universe of firms that professional investors could have actually been using at the time without survivorship bias. For each 10-K and 10-Q filing on EDGAR, the database includes not only the SEC filing date but also the balance sheet date for the quarter/year, so a perfect match with Compustat information can be made.\textsuperscript{16}

For each firm-quarter in the SEC Match Point database, we obtain the SEC filing dates for the period Q4/1995-Q2/2006, to get sufficient representation of firms in the database each quarter; prior to 1996, EDGAR filing was mandatory only for large firms. We include in our sample only those SEC filings made within 55 (100) days for 10-Q (10-K) forms to make sure we exclude delayed filings. We further limit the sample to observations with SEC filing dates for initial 10-Q/10-K filings in the S&P Filing Dates database which also have a matching GVKEY on Compustat and a matching PERMNO on CRSP, so we can retrieve financial statements data from Compustat about these firms and stock return data from CRSP. We further reduce the sample to firms that are listed on NYSE, AMEX or NASDAQ and have a market value and total assets at quarter end, as well as total assets at the end of the prior quarter in excess of $1 million. We further delete observations if the originally reported income before extraordinary items and discontinued operations (Compustat Quarterly item No. 8) is missing; or the originally reported quarterly net operating cash flow (Compustat Quarterly item No. 108) is missing; if market value at the end of the prior quarter is unavailable; or if total assets

\textsuperscript{16} Because companies may file their 10-Q forms late, the filing date itself cannot be a reliable indication for the specific quarter used in the filing.
(Compustat Quarterly item No. 44) at the end of the prior quarter or at the end of the current quarter are missing.

3.3 Variable Definitions

To reduce the survival bias, we use holding periods of 90 days after the SEC filing date if the subsequent quarterly earnings announcement date is missing. If a security is delisted from an exchange before the end of the holding period, we use the delisting return from CRSP if available, and -100% if the stock is forced to delist by the exchange or if the delisting is due to financial difficulties. After delisting, we assume the proceeds are invested in the benchmark size and B/M portfolio. This is the procedure used by Kraft, et al. (2004). We first calculate the buy and hold return on the security during the holding period; then subtract the buy and hold return on a similar size and B/M benchmark portfolio for the same holding period. The benchmark returns are from Professor Kenneth French’s data library, based on classification of the population into six (two size and three B/M) portfolios.\(^\text{17}\) To make sure that our results are not driven by observations with extreme returns as argued by Kraft et al (2004), we delete all extreme 0.5% observations with buy and hold excess returns in any of the two return periods used.

Consistent with the accruals literature, we estimate accruals as earnings minus net operating cash flows, and scale by average total assets during the quarter. We estimate the OCF variable as net operating cash flow for the quarter scaled by average total assets during the quarter. Accruals and OCF are based on the first-reported data in the Charter Oak database, and are not subject to Compustat’s subsequent restatement of data. We estimate the preliminary earnings surprise as IBES (unadjusted for splits) actual EPS minus mean forecasted (unadjusted for splits) EPS by all analysts with quarterly forecasts.

\(^{17}\) [http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data_library.html](http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data_library.html)
in the 90-day period prior to the preliminary earnings announcement, scaled by price per share at quarter end. If there are no analyst forecasts of earnings on IBES, we use preliminary net income (Compustat quarterly item No. 8) minus net income as reported for the same quarter in the prior year, scaled by market value of equity at the end of the previous quarter.

To eliminate the undue influence of outliers and to estimate the returns on hedge portfolios constructed according to various signals, we independently sort all firms into quintiles of various signals each quarter. We then use the scaled quintile rank as the independent variable in regression equations, where the scaling is performed by dividing the ranked quintile (0-4) by 4 and subtracting 0.5. Thus, the intercept in regressions of returns on the signal should be equal to the mean excess BHR for the period, and the slope coefficient on the signal represents the return on the hedge portfolio that is long the highest signal quintile and is short the bottom signal quintile.

To obtain signals about the “tone” and “sentiment” of the MD&A section in the 10-Q or 10-K, we extract the MD&A section and count the number of words in the section. We eliminate cases where the total number of words is less than 30. We also count the number of “positive” and “negative” words as classified by the Harvard’s General Inquirer, after properly handling prefixes and suffixes.18 We define three main variables as our signals, the number of “positive” (“negative”) words, POS (NEG), divided by the number of total words, and (POS-NEG)/(POS+NEG). To identify changes in the “tone” and “sentiment” of MD&A from past filings and to scale signals properly for their variability, we subtract from each signal the mean signal in the SEC filings made within the preceding 400 calendar days, and divide by the standard deviation of the signal

---

in the SEC filings made within the preceding 400 calendar days. We expect high scores on the POS and (POS-NEG) signals to have higher immediate and subsequent returns than those with low scores. Conversely, we expect immediate and subsequent returns on high NEG scores to be lower than those on low NEG scores. Consistent with prior results, we expect firms with high scores on OCF and earnings surprises to have greater immediate and subsequent returns than those with low scores. The converse should hold for accruals.

To be included in our sample, we require firms to have data about the three “tone” signals (POS-NEG, POS, NEG), earnings surprise, OCF, accruals, the short window returns around the SEC filing (i.e., days [-1,+1], where day 0 is the SEC filing date), and the drift return from two days after the SEC filing through one day after the preliminary earnings announcement for the subsequent quarter. The final sample contains 170,056 observations (firm-quarters), with 1,972 in Q1/1995 (minimum per quarter in our sample) climbing to a high of 4,700 in Q2/1999 (the maximum for a quarter) and ending with 3,308 in Q2/2006. Thus, there is sufficient number of observations for each of the quarters in our sample period.

Table 1 provides summary statistics about our sample. As can be seen, our sample consists of firms with a wide distribution of sizes. The sample median market value is $199 million and the mean is $2.28 billion. The median price per share is $12.08 with a mean of $31.02; recall that there is a minimum price per share of $1.00 for sample inclusion. Thus, we have a wide distribution of firm size and price per share. The table also indicates that slightly more than 50% of the firm-quarters have analyst forecasts of earnings on IBES with a median number of forecasts (when available) of 3. Consistent
with prior studies the mean and median accruals are negative, largely due to the effects of depreciation. The mean and median SUEs are roughly zero indicating that our earnings forecast models are reasonably good for the median firm. It is interesting to note that the number of positive words is usually greater than the number of negative words in MD&A disclosures, indicating a possible optimistic tone and sentiment in MD&A disclosures on average. This also requires us to adjust for “expected” number of positive/negative words by subtracting the mean signal in the prior 400 days. The positive and negative signals indicate a slight skewness, with the means slightly larger than the medians.

(Insert Table 1 about here)

4. Results

Table 2 shows the mean excess returns for three representative subgroups of our sample firms formed using different signals, where mean excess returns is defined as the buy and hold returns (BHR) on a stock minus the average returns on a matched size-Book to Market (B/M) portfolio over the days [-1. +1], with day 0 identified as the SEC filing date. Firms are classified into three groups using bottom 20%, middle 60%, and top 20%. Consistent with the prior literature about short window reactions and drift after the preliminary earnings announcement, firms in the bottom (top) SUE quintile have a mean excess return of -1.2% (+0.8%) in the three-day window centered on the SEC filing. A similar pattern is evident for the earnings components of OCF and accruals, with a mean excess return of -0.6% (+0.2%) for the bottom (top) OCF quintile, and -0.3% (+0.1%) for the bottom (top) accruals quintile.

(Insert Table 2 about here)
The interesting observation in this table pertains to the tone and sentiment signals in the MD&A sections. Both positive and negative sentiments are associated with the significant short window mean excess returns in the expected direction. The bottom (top) negative tone and sentiment quintile has mean excess returns for the short window around the SEC filing of 0.1% (-0.4%). The converse is evident for the positive and (positive-negative) signals, where the bottom quintile have means of -0.2% and -0.3%, respectively, and the top quintiles mean excess returns of -0.1% and 0.1%, respectively. Thus, we see that the spread in mean excess returns between top and bottom quintile is the largest for the negative signal, followed by the (positive-negative) signal and finally the positive signal.

Table 3 provides a correlation matrix between the excess return in the three-day window centered on the SEC filing, BHR-Filing, the subsequent drift, BHR drift, the control variables, namely, Accruals, OCF, and SUE, and the tone and sentiment measures. As is to be expected, accruals and OCF are strongly and negatively correlated (-0.550), and the differential tone variable (pos-neg) is also strongly correlated with each of the other tone variables (0.540 and -0.670). Interestingly, the correlation between the two pure tone variables, (negative and positive) is negative but not high (-0.029). Consistent with the evidence in Table 2, SUE, accrual and OCF are positively and significantly correlated with the short window excess return around the SEC filing date, BHR-Filing (0.078, 0.017 and 0.031, respectively). The differential tone signal (pos-neg) tone signal exhibits significant positive correlation (0.014) with the short window excess return around the SEC filing, with the negative signal exhibiting a significant negative
correlation of -0.020, and the positive signal exhibiting positive but insignificant correlation.

(Insert Table 3 about here)

Consistent with prior literature, the excess return during the period from the SEC filing through the subsequent quarter’s earnings announcement, BHR-Drift, is negatively correlated with accruals (-0.019) and positively correlated with both SUE and OCF (0.045 and 0.18, respectively). The negative tone signal is significantly negatively correlated with BHR-drift (-0.010), whereas the positive signal is significantly positively associated with BHR-Drift (0.008). The differential signal (Positive-Negative), is however, strongly positively correlated the drift, BHR-Drift, at 0.014. Note that both OCF and SUE are positively and significantly correlated with the differential (Pos-Neg) and positive tone signals, and negatively with the negative tone signal. The accruals signal is negatively correlated with the positive tone signal, but positively correlated with the differential tone signal and negatively correlated with the negative tone signal, contrary to what can be expected. This indicates that we need to control for SUE, OCF and accruals in our tests.

Table 4 presents the results of our Fama-Macbeth type regressions for returns around the SEC filing dates (BHR-Filing) regressed on different sets of financial and tone signals, namely accruals, OCF, SUE, and our three tone signals. Each column records the intercept and slope for the regression of the three-day excess return centered on the SEC filing date, BHR-Filing, on different combination of these signals. Recall that the slope coefficients can be interpreted as a return on a hedge portfolio that is long in the top quintile and is short the bottom quintile for a specific signal. Note further that preliminary
earnings announcements typically precede the SEC filings, so that “new” information to market participants around the SEC filing date is in the form of OCF and accruals, as well as the tone signals through the newly disclosed MD&A section. Thus, columns 1-3 in the table examine the incremental information in the tone of the MD&A section given information about accruals released in the SEC filing. The accruals signal is positively and significantly associated with the short window returns. Although this may seem contradictory to prior results about accruals, i.e., negative association with returns, the prior evidence is about the association of accruals with future returns instead of the contemporaneous returns used in Table 4. Note that two of the tone variables, the negative and the differential tone signals are significantly (with the correct signs) associated with the short window returns around filing, even after controlling for accruals. The positive signal has the correct positive association, but its coefficient is not significantly different from zero. A similar picture emerges for the OCF variable in columns 4-6 of Table 4, except that the OCF variable is more strongly associated with the short window returns than the accrual signal. Finally, columns 7-9 present the associations of the tone signals with short window returns around the SEC filings, conditional on the previously disclosed earnings surprise. Note that the return on the hedge portfolio constructed according to the earnings surprise SUE is higher than the hedge return on both accruals and OCF, implying that market participants get further confirmation from SEC filings about the original earnings surprise. Note further that the differential and negative tone signals are still significantly associated with short window returns beyond SUE, whereas the positive signal does not have any incremental association with short window returns beyond SUE. Thus, Table 4 results show that
market reactions to two of the tone signals are incremental to the widely used financial signals of SUE, accruals and OCF.

(Insert Table 4 about here)

Table 5 is the counterpart of Table 2 for drift returns instead of the short window returns around SEC filing dates used in Table 2. The table reports mean excess returns, i.e., buy and hold return on a stock minus the average return on a matched size-B/M portfolio, from two days after the SEC filing through one day after the subsequent quarter’s preliminary earnings announcement (BHR-Drift). As the table shows and consistent with the post earnings announcement drift literature, the bottom (top) quintile of SUE had a mean drift of -0.6% (5.5%). Similarly, the mean excess drift returns on OCF for the bottom (top) quintiles is 1% (3.1%). However, inconsistent with prior studies, the drift return on the bottom (top) quintile is 0.3% (0.4%). Thus, the accruals signal does not seem to work well in isolation using quarterly accruals. More interestingly, the all tone signals seem to work as expected with the differential tone signal having the largest spread between bottom and top quintiles, 0.5% and 1.9%, respectively. The positive (negative) signal shows mean drift return of 0.8% (1.7%) for the bottom quintile and 2.0% (0.4%) for the top quintile. Another interesting observation in Table 5 is that SUE and the tone signals provide monotonic mean returns across the three groups, whereas both accruals and OCF deviate from such monotonic relationship.

(Insert Table 5 about here)

Table 6 is the counterpart of Table 4 where the dependent variable is the drift excess returns from two days after the SEC filing through one day after the subsequent earnings announcement, (BHR-Drift). It reports mean coefficients of cross-sectional
quarterly regressions in a Fama and MacBeth (1973) manner. The first three columns report the results of using the three tone variables in addition to accruals. The hedge portfolio return on accruals is negative, as expected from prior studies (low accruals imply future positive returns) of about -2.4% per quarter, which is similar to Sloan’s (1996) -10% annually. It should be noted that all three tone variables add significantly strong associations with drift returns, where the differential tone signal adds 1.7% to the quarterly return, the positive signal 0.9%, and the negative signal -1.3%. The OCF signal in columns 4-6 has the same hedge return of about 2.4% per quarter, although it is not significantly different from zero at conventional levels. However, the three tone variables significantly add to the drift similar amounts to those added when accruals were used. Finally, the SUE signal in columns 7-9 has the highest quarterly hedge drift return of about 5.8%, but even then the three tone signals add significant amounts to the drift hedge return, with the differential tone signal (positive, negative) adding 1.2% (0.8%, -0.8%) per quarter. Thus, the three tone signals not only contribute incrementally to associations of financial variables with short-window returns around SEC filings, but also to drift in returns through the following earnings announcements.

(Insert Table 6 about here)

Table 7 records the potential payoffs to holding quarterly hedge strategies in stock using the extreme quintiles of the signals, i.e., holding long (short) positions in the top (bottom) quintile of SUE, OCF, the differential tone signal (positive minus negative) and positive tone signal. The converse strategy is used to construct a portfolio based on accruals and the negative tone signal. The hedge portfolio return is held from two days after the SEC filing through one day after subsequent quarter’s preliminary earnings
announcement. The hedge portfolio is formed each quarter based on the extreme signal quintiles for that quarter. When the hedge portfolio is based on more than one signal, stocks in the portfolio have to be in the extreme quintile for both signals. As can be seen in Table 7, SUE has the highest payoff with a mean quarterly return of 6.0%. This is followed by accruals (2.4%) and OCF (2.2%). The three tone signals also have significant payoff of 1.3% for the differential signal, 1.2% for the positive signal and 1.2% for the negative signal. When the differential tone signal is combined with SUE, the hedge portfolio quarterly return is 7.2%, showing that most of the information in the differential tone signal is orthogonal to that in SUE, since the resulting hedge portfolio return is roughly the sum of the two independent hedge portfolio returns (6.0%+1.3%). Note, however, that this combined signal hedge portfolio is less diversified with an average of 368 stocks each quarter compared to 1,580 stocks when one signal is used. Note also that the table reports the results of a statistical test that the mean drift return on the combined portfolio is significantly larger than that of SUE alone. It shows that the mean quarterly difference is 1.2% with a t-statistic of 1.36 (0.1802, two-sided significance level). The differential tone signal is much more effective in combination with accruals and OCF, where it actually adds 2.1% and 1.8%, respectively, more than the 1.3% when it is used alone. These additional returns are statistically significant with t-statistics of 1.95 and 2.55 (0.0580 and 0.0146, two sided significance levels). Consistent with the results of Battalio et al (2006), when SUE is paired with accruals, the hedge portfolio yields a mean quarterly return of 9.7%. However, when the differential tone signal is added to the combination of SUE and accruals, the hedge portfolio return now has a mean quarterly drift return of 13%, but with only about 71 stocks on average. Still, the incremental 3.2%
to the drift return due to the differential tone variable is statistically significant with a t-statistic of 1.85 (0.0716, two sided significance level). Thus, the tone signals based on the MD&A section of the 10-Q or 10-K Forms add incrementally to the financial information conveyed by earnings surprises, accruals and OCF.

(Insert Table 7 about here)

5. Conclusions

This study investigates whether non-financial information contained in the MD&A section of SEC filings is associated with excess market returns in the short window around SEC filings and with drift excess returns over the period from two days after the SEC filings through the subsequent quarter’s preliminary earnings announcements. If management has private information about the firm’s prospects, and if management shares a portion of this information with investors through truthful disclosures in SEC filings, then market reactions as well as delayed market reactions should be associated with the non-financial information disclosed by management in the MD&A section. However, investors need to assess whether the non-financial information has favorable or unfavorable implications for contemporaneous and future returns. As a crude measure of whether the non-financial information is favorable or unfavorable, this study compares the frequency of “positive” words, “negative” words or the difference between them to the same frequency in recent MD&A sections of the same firm. If managers’ assessments of future prospects become more negative (positive), they are likely to use more “negative” (“positive”) words in their disclosures. This study uses an
established classification of words into “positive” and “negative” categories, which was used by many previous studies.

Our results indicate that the non-financial signals based on changes in the tone of the MD&A section from the recent past are significantly correlated with short window contemporaneous returns around SEC filing dates, even after controlling for financial information available in either the SEC filings (accruals and OCF) or the preliminary earnings announcements (earnings surprises). Our results also show that the non-financial tone signals are significantly correlated with drift excess returns, even after controlling for accruals, OCF, and to some extent earnings.

The combined evidence in this study shows that market participants seem to behave as if they use non-financial information from MD&A disclosures (or other information that is correlated with it), in addition to the financial information provided routinely by firms. This indicates that the MD&A sections do have information content, and that the SEC requirement to provide these discussions by management seems to be justified. Our results are, of course, limited by the perfunctory manner in which we analyze the MD&A section – the mere counting of positive and negative words. Intuitively, stronger results may be obtained by using more sophisticated analytical tools that would classify better the contents of the MD&A as favorable or unfavorable.

Our study contributes to various constituencies. Academic studies that (i) are interested in assessing the effects of non-financial information on security prices, or (ii) are interested in the effects of the MD&A disclosures, or (iii) are concerned with managerial private information and the forms used to convey it to investors, may benefit from our analysis. Regulators may use the results of this study to assess the benefits of
mandatory non-financial disclosures. Professional investors may use procedures similar to ours to help improve portfolio selection based on publicly available information. However, we emphasize again that this study provides just one simple way of analyzing the rich set of non-financial information that is potentially available to investors. Future studies can be designed to extract finer non-financial information.

Notes:
1. The sample is based on 10-Q and 10-K filings for quarters spanning Q4/1995-Q2/1996. SEC filings are retrieved from S&P’s SEC Match Point database. Sample firms are those with available data, and passing the selection criteria described in the text.
2. (Positive-Negative) signal is based on the number of positive words minus the number of negative words, scaled by the sum of positive and negative words. Positive (Negative) signal is based on the number of positive (negative) words divided by the total number of words. For all three signals, the signal subtracts the average signal in all SEC filings made in the prior 400 days, and divides by the standard deviation of the signal in the same period.
3. No. of Positive (Negative All) Words is the total number of positive (negative all) words in the MD&A section of the SEC filing.
4. When there are no analyst forecasts for the quarter, SUE is calculated from the Compustat quarterly database as preliminary income (Quarterly item 8) for quarter t minus as-first-reported income for quarter t-4, scaled by the market value of equity at the end of quarter t-1. When there is at least one analyst forecast for quarter t on IBES, the SUE is calculated as the actual I/B/E/S EPS minus the mean analyst forecast during the 90-day period before the disclosure of earnings, scaled by the price per share at the end of the quarter.
5. Accruals (Net OCF)/Average Assets equals income before extraordinary items and discontinued operations minus cash from operations (OCF), scaled by average total assets during the quarter.
6. BHR is the buy and hold return on a stock minus the average return on a matched size-B/M portfolio. One window spans two days after the SEC filing through one day after the subsequent quarter’s preliminary earnings announcement. The Filing window spans days [-1,+1], where day 0 is the SEC filing date.

Notes:
1. The table presents Pearson correlations between regression variables, which include excess buy and hold returns (BHR) on scaled signal ranks. Each signal is assigned its quintile rank, is divided by 4, and 0.5 is subtracted to obtain the scaled signal rank. The table is based on all available observations. Bold entries represent correlations that are statistically different from zero with a significance level below 5%.
2. (Positive-Negative) signal is based on the number of positive words minus the number of negative words, scaled by the sum of positive and negative words. Positive (Negative) signal is based on the number of positive (negative) words divided by the total number of words. For all three signals, the signal subtracts the average signal in all SEC filings made in the prior 400 days, and divides by the standard deviation of the signal in the same period.
3. When there are no analyst forecasts for the quarter, SUE is calculated from the Compustat quarterly database as preliminary income (Quarterly item 8) for quarter t minus as-first-reported income for quarter t-4, scaled by the market value of equity at the end of quarter t-1. When there is at least one analyst forecast for quarter t on IBES, the SUE is calculated as the actual I/B/E/S EPS minus the mean analyst forecast during the 90-day period before the disclosure of earnings, scaled by the price per share at the end of the quarter.
4. Accruals (OCF) /Average Assets equals income before extraordinary items and discontinued operations minus cash from operations (OCF), scaled by average total assets during the quarter.
5. BHR-Filing is the buy and hold return on a stock minus the average return on a matched size-B/M portfolio over the days [-1,+1], where day 0 is the SEC filing date. BHR-Drift is the excess BHR over the period from two days after SEC filing through one day after the preliminary earnings announcement in the subsequent quarter.

**Notes:**
1. The table presents mean coefficients from 43 quarterly regressions of the excess buy and hold return (BHR) around SEC filing dates on scaled signal ranks. Each signal is assigned its quintile rank, is divided by 4, and 0.5 is subtracted to obtain the scaled signal rank. Quarterly regressions have on average 3,955 observations. Bold entries represent correlations that are statistically different from zero with a significance level below 5%. Significance levels are based on the standard error of the coefficient across the 43 quarterly regressions in a manner of Fama and MacBeth (1973).
2. (Positive-Negative) signal is based on the number of positive words minus the number of negative words, scaled by the sum of positive and negative words. Positive (Negative) signal is based on the number of positive (negative) words divided by the total number of words. For all three signals, the signal subtracts the average signal in all SEC filings made in the prior 400 days, and divides by the standard deviation of the signal in the same period.
3. When there are no analyst forecasts for the quarter, SUE is calculated from the Compustat quarterly database as preliminary income (Quarterly item 8) for quarter t minus as-first-reported income for quarter t-4, scaled by the market value of equity at the end of quarter t-1. When there is at least one analyst forecast for quarter t on IBES, the SUE is calculated as the actual I/B/E/S EPS minus the mean analyst forecast during the 90-day period before the disclosure of earnings, scaled by the price per share at the end of the quarter.
4. Accruals (OCF)/Average Assets equals income before extraordinary items and discontinued operations minus cash from operations (OCF), scaled by average total assets during the quarter.
5. BHR-Filing is the buy and hold return on a stock minus the average return on a matched size-B/M portfolio over the days [-1,+1], where day 0 is the SEC filing date.

### Notes:
1. The table presents mean excess returns from two days after the SEC filing through one day after the subsequent preliminary earnings announcement for sub-groups based on various signals. Bold entries represent mean excess returns that are statistically different from zero with a significance level below 5%.
2. (Positive-Negative) signal is based on the number of positive words minus the number of negative words, scaled by the sum of positive and negative words. Positive (Negative) signal is based on the number of positive (negative) words divided by the total number of words. For all three signals, the signal subtracts the average signal in all SEC filings made in the prior 400 days, and divides by the standard deviation of the signal in the same period.
3. When there are no analyst forecasts for the quarter, SUE is calculated from the *Compustat* quarterly database as preliminary income (Quarterly item 8) for quarter t minus as-first-reported income for quarter t-4, scaled by the market value of equity at the end of quarter t-1. When there is at least one analyst forecast for quarter t on IBES, the SUE is calculated as the actual *I/B/E/S* EPS minus the mean analyst forecast during the 90-day period before the disclosure of earnings, scaled by the price per share at the end of the quarter.
4. Accruals (OCF) /Average Assets equals income before extraordinary items and discontinued operations minus cash from operations (OCF), scaled by average total assets during the quarter.
5. The excess return is the buy and hold return on a stock minus the average return on a matched size-B/M portfolio from two days after the SEC filing date through one day after the subsequent quarter’s preliminary earnings announcement.

Notes:
1. The table presents mean hedge returns based on 43 quarters. Each quarter, long (short) positions are held in the top (bottom) quintile, except for NEG and accruals, where quintiles are reversed. The hedge portfolio is held from two days after the SEC date through one day after the subsequent quarter’s preliminary earnings announcement. When hedge portfolios are based on more than one signal, only firms falling into the most extreme quintiles of both signals are held in the portfolio. Bold entries represent hedge returns that are different from zero with significance levels below 5% (one-sided for differences in portfolios). Portfolios are numbered 1-11.
2. (Positive-Negative) signal is based on the number of positive words minus the number of negative words, scaled by the sum of positive and negative words. Positive (Negative) signal is based on the number of positive (negative) words divided by the total number of words. For all three signals, the signal subtracts the average signal in all SEC filings made in the prior 400 days, and divides by the standard deviation of the signal in the same period.
3. When there are no analyst forecasts for the quarter, SUE is calculated from the Compustat quarterly database as preliminary income (Quarterly item 8) for quarter t minus as-first-reported income for quarter t-4, scaled by the market value of equity at the end of quarter t-1. When there is at least one analyst forecast for quarter t on IBES, the SUE is calculated as the actual I/B/E/S EPS minus the mean analyst forecast during the 90-day period before the disclosure of earnings, scaled by the price per share at the end of the quarter.
4. Accruals (OCF) /Average Assets equals income before extraordinary items and discontinued operations minus cash from operations (OCF), scaled by average total assets during the quarter.
5. The excess drift return is the buy and hold return on a stock minus the average return on a matched size-B/M portfolio from two days after the SEC filing date through one day after the subsequent quarter’s preliminary earnings announcement.
6. The t-statistics and significance levels are based on the 43 quarterly hedge returns.
7. N is the average total number of firms in the hedge portfolio.
8. Diff vs. Port is a comparison of the return on the row’s hedge portfolio minus the return on the hedge portfolio indicated in the column. For example, the hedge return on (POS-NEG) Signal+SUE in row 7 is compared to the hedge portfolio return on SUE in row 6. It measures the incremental return obtained by using both SUE and the (POS-NEG) Signal.
