Abstract

We present an asymmetric information model to examine preferential allotments of equity. We show that the optimal investment-financing decision of firms depends on the interaction between information asymmetry and the capital constraints faced by owner-managers. Thus, our model simultaneously determines the investment/under investment choice as well as the choice between private placements to owner-managers, rights offerings and private placements to private equity players, if the firm decides to invest. Further, our model predicts that announcement period returns for preferential allotments should be (1) positive; (2) dependent on regulatory constraints that determine the issue price; (3) positively related to volatility; (4) unrelated to insider ownership; (5) negatively related to illiquidity; and (6) unrelated to proxies of manipulation. Our model also predicts that (7) the announcement effects for private placements to private equity investors should be lower than those of private placements to owner-managers. We empirically test our model’s predictions, along with others from the related literature on private placements, in a sample of preferential allotments issued in the Indian capital markets during 2001-2009 and report empirical evidence that is largely consistent.

JEL Classification: G 18.
Keywords: Private Placement, Preferential Allotment, Business Groups, Underinvestment
1 Introduction

Preferential allotment of equity shares is a commonly used financing mechanism in Indian capital markets. This arrangement typically occurs in the form of block deals issued to firm managers, but such allotments can also be made to private equity players, banks and other financial institutions.

In principle, a preferential allotment is nothing but a private placement of equity. However, since the corporate governance context in India differs significantly from that in developed countries, it merits special treatment. In emerging markets like India, many businesses are family-controlled and there is a significant overlap between a firm’s management and its owners. Business families in India typically retain substantial stakes in the companies under their control and provide capital for new projects/companies. As a consequence, preferential allotments are often made to owner-managers; thus, they are initiated by owners and also subscribed by owners, a situation that is rife with conflicts of interest. For instance, owner-managers can issue equity shares to themselves during times of market undervaluation or much worse, deliberately manipulate their share prices downward in order to buy shares at lower prices. Although the potential for such managerial self-dealing has been generally recognized, the degree to which it can occur in family-controlled firms is much more significant, which has largely been ignored, in the private placement literature, so far.

Despite this negative externality, regulatory authorities have encouraged the growth of the preferential allotment market, mainly because business families are important sources of new capital in emerging economies. Hence, other than placing a restriction on the permissible issue price in a preferential allotment, there is generally no regulation prohibiting preferential allotments to owner-managers. In fact, the market for preferential allotments has grown significantly over the last few decades. For example, in 2008-2009, Indian firms raised the equivalent of US$8.96 billion through preferential issues, compared to US$0.50 billion, US$0.21 billion, and US$2.21 billion through rights offerings, outside equity issues (initial public offerings (IPOs) and secondary equity offerings (SEO)), and qualified institutional placements (QIPs), respectively.\(^1\)

\(^1\)Family businesses tend to retain managerial control in India, because the judicial process is fraught with delay, and the enforcement of legal rights is lax, as in other emerging markets. As a consequence, merging the roles of ownership and management is a key device to avoid the agency problem created by separation of ownership and management.

\(^2\)Source: NSE Fact Book 2013-2014. The figures are converted from Indian Rupees (INR) to US dollars (USD) at the exchange rate 1 USD = 60 INR, which prevailed at that time.
We analyze this problem in depth by presenting an asymmetric information model to explain the prevalence of preferential allotments. Our paper contrasts with Myers and Majluf (1984) and subsequent papers in the literature, which rule out the possibility of managers subscribing to their firm’s equity issues. This assumption is reasonable in markets where (the lack of) managerial wealth and managerial risk aversion constrain managers from participating in equity issues (an exception being management buy-outs). However, in countries like India, family-controlled business groups dominate the economic landscape. In such economies, promoters of firms often continue to operate them as owner-managers. These promoters usually have access to other resources, for example through other firms they control, which allows them to participate in subsequent equity offerings. Our model, therefore, extends our understanding of the financing decisions made by managers in many countries, particularly in the emerging economies. However, the model is not restricted to these markets since the implications of the model are generally applicable to any market where owner-managers have the choice of issuing equity to themselves in the presence of regulatory constraints. By including a third alternative of issuing equity to owner-managers in the form of preferential allotments (and rights offerings), in addition to the conventional choice between using internal resources and seeking outside financing, we generalize the Myers and Majluf (1984) model.

Our model is built around two key features: (i) information asymmetry between outsiders and insiders regarding the hidden value in a firm and (ii) capital constraints faced by owner-managers. We show that the optimal investment-financing decision of firms depends on the interaction between information asymmetry and capital constraints faced by owner-managers. In the case of weak signals about hidden value, insiders issue equity to outsiders. When they see signals of intermediate strength about the firm’s hidden value, insiders opt for a rights offering alternative or the private equity alternative, depending on the severity of their capital constraints. In the presence of sufficiently strong signals about the hidden value, however, insiders opt for a preferential allotment of equity to themselves, but if they are severely capital constrained, they will prefer to underinvest. Thus, our model simultaneously determines the investment/underinvestment choice as well as the choice between private placements to owner managers, rights offerings and private placements to private equity players, if the firm decides to invest. These results can be seen as a generalization of the Myers and Majluf model to the situation where insiders are allowed to finance the firm. A key implication arising out of this model is that, if owner-managers do not face severe capital constraints, private placements to owner-managers...
can mitigate, if not eliminate, the underinvestment problem.

While the “no underinvestment” outcome is clearly beneficial from a social welfare perspective, allowing insiders to participate in equity issues is fraught with the danger of managerial self-dealing. Insiders have incentives to manipulate share prices to lower levels prior to issuing shares to themselves. Therefore, financial markets that permit insider equity financing often impose regulations on the issue price to counter these incentives. Thus, any empirical examination of our model will necessarily be influenced by regulatory constraints imposed on private placements to insiders. In this study, we validate the above claims by examining a sample of preferential allotments in India.

Equity issues in India are regulated by the Indian securities market regulator, the Securities and Exchange Board of India (SEBI). The key feature of SEBI’s regulation relevant to our model is that the issue price in a private placement cannot be lower than the maximum of the most recent market price and the average market price in the previous six months. This regulation is clearly aimed at discouraging managers from “timing” the market and also from “manipulating” stock prices in order to issue shares to themselves at prices lower than their true market value (managerial self-dealing). Hence, our model explicitly incorporates this regulatory pricing rule, as well as the possibility of price manipulation by insiders, in developing clear and testable implications.

Our work is related to the work of Hertzel and Smith (1993) in their statement of the Certification Hypothesis, in that it too deals with information asymmetry. Their model largely addresses the certification role played by private equity investors in private placements whereas our model is designed for private placements to owner-managers, where certification clearly has no role to play, but information asymmetry still matters. At the same time, we account for the possibility of certification by private equity investors; thus, our model comprehensively captures the role of information asymmetry in preferential allotments. The hypotheses from our model can be classified as part of the broad Undervaluation Hypothesis, as conjectured in Barclay et al. (2007), page 478: “This situation, in many ways, is the reverse of Myers and Majluf (1984). In that analysis, management acting in the interests of all current shareholders issues equity to outsiders when management believes the stock to be over-valued. In this explanation, managers

3Gomes and Phillips (2012) show that asymmetric information plays a major role in the choice of security type within public and private markets and in the choice of market in which to issue securities.
issue stock to themselves when they believe their stock to be undervalued.”

Since underinvestment is not directly observable, we develop empirically testable hypotheses that confirm the role of information asymmetry in preferential allotments. Our model predicts that announcement period returns for preferential allotments should be (1) positive; (2) dependent on regulatory constraints that determine the issue price; (3) positively related to the volatility of prices; (4) negatively related to the illiquidity of the stock; (5) unrelated to the insider ownership; and (6) negatively related to proxies of manipulation. Our model also predicts that (7) announcement effects for preferential allotments to private equity investors should be lower than those of preferential allotments to insiders. We empirically test the model’s predictions on a sample of 164 preferential allotments issued in the Indian capital markets during 2001-2009 and report empirical evidence largely consistent with the model. In addition to the empirical predictions of our model, we also find that (8) firms affiliated to business groups experience lower but statistically insignificant announcement period returns compared to stand-alone firms; and (9) preferential allotments made to (active) private equity investors do not experience higher announcement period returns than those made to banks or financial institutions.

Our paper is also related to the extant empirical literature on private placements. Firstly, Wruck (1989) suggests that private placements are used to attract active shareholders who provide monitoring benefits (Monitoring Hypothesis). More recently Wu (2004) and Barclay et al. (2007) find that private placements are used to bring in passive shareholders (Managerial Entrenchment Hypothesis). Wruck and Wu (2009) find that the pre-placement relationship with the investors matters in private placement. They find that new relationships to improve corporate governance leads to positive abnormal returns. Lastly, Wu (2004), Baek et al. (2006) and Barclay et al. (2007) show that private placements to owner-managers are made at significant discounts (Managerial Self-Dealing Hypothesis), which is a variation of the Managerial Entrenchment Hypothesis. The most recent empirical evidence in the U.S. supports the Managerial Entrenchment and the Managerial Self-Dealing Hypotheses.

The empirical evidence presented in this study is largely supportive of the Undervaluation Hypothesis of our model. All our key findings are robust in the sense that they persist after controlling for manipulation. Our analysis also sheds light on the Monitoring, Certification and Entrenchment Hypotheses that have been proposed in the existing literature on private placements. Our results show little support for the latter three in the context of Indian capital markets.
In summary, the contribution of our paper is to extend the Myers and Majluf (1984) framework to examine the financing decisions of firms in emerging markets. Apart from developing the model, we are able to test its predictions with data from the Indian securities market, where owner-managers dominate the capital market and the regulatory environment is different from that in the U.S. and Europe, the focus of many of the prior studies. Overall, our empirical evidence corroborates the Myers and Majluf (1984) framework, after accounting for the competing motivations of private placements.

The paper is organized into five sections. A brief background on the regulation of preferential allotments in India is presented in Section 2. Section 3 presents our theoretical model and the corresponding empirical implications and testable hypotheses that follow from the model. (The proofs are presented in Appendix 1.) Section 4 describes the data and certain methodological issues, and also presents the results of the empirical analysis. Section 5 concludes.

2 Preferential Allotments and Regulatory Restrictions in the Indian Securities Market

Before developing a model to generate testable empirical implications related to the Undervaluation Hypothesis, we first discuss the regulatory environment affecting the private placement market in India. This description provides essential background that helps to present the salient features of our theoretical model. The Indian capital market is regulated by SEBI. In India, preferential allotments of listed companies - often referred to as preferential issues or preferential allotments - are quite popular.\(^4\) It should be emphasized that not all preferential allotments are made to owner-managers (or promoters, as they are known in local parlance).\(^5\) (Henceforth, we will use the terms preferential allotment and private placement interchangeably.) Preferential allotments are also made to private equity players, banks and financial institutions. However, all

\(^4\)The popularity of preferential allotments seems to have increased in recent times since the introduction of a grading system for IPOs in India provided by major rating agencies or their affiliates. This somewhat unusual system of IPO grading was introduced to provide a mechanism for assessing issuer quality and thereby restricting the entry of fly-by-night operators into the market. Deb and Marisetty (2010) find that the grading of IPOs has information content only for retail investors; institutional investors do not appear to make their IPO investment decisions on this basis. Hence, it is likely that issuers who target institutional investors are better off going for preferential issues, as they eliminate the costs associated with grading and related expenses incurred in public offerings.

\(^5\)Shareholders do not enjoy pre-emptive rights in India.
preferential allotments are subject to SEBI’s pricing regulations, which are described below.

2.1 Pricing of Preferential Issues

The pricing of preferential equity issues in India is governed by the following regulations, with the relevant phrases italicized: “The issue of shares on a preferential basis (equity shares/ fully convertible debentures/ partly convertible debentures) can be made at a price not less than the higher of the following: (a) The average of the weekly high and low of the closing prices of the related shares quoted on the stock exchange during the six month period preceding the relevant date; or (b) The average of the weekly high and low of the closing price of the related shares quoted on a stock exchange during the two week period preceding the relevant date.” The relevant date for this purpose is the date 30 days prior to the date on which the meeting of the general body of shareholders is held.

Figure 1 illustrates the SEBI pricing rule. For the purposes of illustration, the price histories of two firms, Reliance Infra and HEG, are displayed on the graph. For Reliance Infra, prices had been increasing. Thus, the average price in the two-week period prior to the relevant date is greater than the average price in the six-month period prior to the relevant date. SEBI rules force the firm to issue new equity at a price greater than (or equal to) the higher of these two prices, namely, the average price in the two-week period prior to the relevant date.

---

Figure 1: SEBI regulations on the issue price in a preferential allotment

This figure is an example of the preferential allotments of two firms, namely Reliance Infra Limited and HEG Limited. The figure has number of trading days before the relevant date (date 0) on the x-axis and the corresponding daily prices for those days on the y-axis. As per SEBI regulations, the issue price should be the higher of either the two-week average of the weekly High-Low prices or the six-month average of the weekly High-Low prices prior to the relevant date. The relevant date is itself 30 days (or 22 trading days) prior to the date of the Extraordinary General Meeting of shareholders held to approve the issue. Hence, for Reliance Infra, the SEBI-mandated issue price is the two-week average weekly High-Low price, whereas, for HEG, the SEBI-mandated issue price is the six-month average weekly High-Low price.
Exactly the converse situation arises for HEG, whose prices had been generally declining. SEBI pricing rules imply that the issue price should exceed the average price in the six-month period prior to the relevant date. In general, if prices are declining, the (lower bound on the) issue price is determined by the historical average price, and if prices are increasing, the (lower bound on the) issue price is determined by more recent valuations. This arrangement ostensibly protects minority shareholders from managerial self-dealing.\footnote{In addition to pricing restrictions, there is also a “lock-in” period of three years from the date of allotment. This rule prevents “flipping” by preferential allottees for short-term gains based on privileged information. SEBI’s norms require the issuer to provide the following information to the stock exchange: (i) the objective of the preferential allotment, (ii) the intention of the promoters and other related parties to subscribe for the offer, (iii) the shareholding pattern before and after the offer, (iv) the proposed time within which the allotment will be completed, and (v) the identification of the proposed allottees and the percentage of post-preferential issue capital that may be held by each of the promoters. These disclosures are meant to provide transparency regarding the use of the proceeds of the issue as well as the process of allotment of the issue to investors.}

3 Model and Testable Implications

We now present a variation of the Myers and Majluf (1984) model for analyzing preferential allotments. In this economy, firms are managed by an individual shareholder or a subset of shareholders (we refer to these investors as owner-managers). Consider a firm that faces a positive NPV investment opportunity. By assumption, the firm does not have enough resources to fund this project internally - it has to be funded with external capital. It can raise capital either in the form of an equity issue to outsiders (we refer to this as outside equity or OE), or in the form of a rights offering (we refer to this alternative as RO), or in the form of a preferential allotment placement to the owner-managers, private equity investors or other associates such as banks. We refer to preferential allotments to owner-managers as OM and preferential allotments to a combination of owner-managers and private equity investors as PE. The basic model considers preferential allotments to owner-managers only.\footnote{Preferential allotments to owner-managers differ from rights issues, which are offered to all shareholders on a pro-rata basis. In terms of modeling, a rights issue is conceptually a hybrid between a preferential allotment placement and an outside equity issue because some existing shareholders (owner-managers) are informed while the remaining shareholders are uninformed (as would be the case for outside equity participants).} Later, we consider the implications of preferential allotments to a combination of owner-managers and private equity investors. The firm also has the choice of rejecting the positive NPV project, thereby underinvesting (we refer to this situation as UI for “Underinvestment”. Similar to the Myers and Majluf setup, we only consider equity capital as a new financing choice, under the assumption that the capital structure choice has already been made.
There are three dates in our model: \( \tau = -1, 0 \) and \( +1 \). Firm value consists of three components: value due to assets-in-place (AIP), hidden value (HV), which characterizes the asymmetric information about assets-in-place, and value due to a positive NPV investment opportunity (IO), about which there is no information asymmetry.

The payoffs on the three components of the firm value are uncertain at date \( \tau = -1 \), but realizations of all these payoffs occur on the liquidation date \( \tau = +1 \). To keep the model simple and intuitive, we consider a two-state economy (with equal probabilities in each state). Thus, all payoffs arise in a binary form. Further, we assume risk-neutral participants and normalize the risk-free rate to 0, without loss of generality. Figure 2 provides an overview of the model structure, which is described in detail below.

3.1 Assets-in-Place (AIP)

At date \( \tau = -1 \), the market views the firm as consisting of assets-in-place, whose terminal (date \( \tau = +1 \)) payoff is of the form \( \{s, 0\} \) with equal probability. The up-state payoff \( s \) is itself a random variable; at date \( \tau = -1 \), the market believes that \( s \) can either be \( h \) (for “high”) or \( l \) (for “low”) with equal probability. At date \( \tau = 0^- \), the market learns whether \( s \) is \( h \) or \( l \) with certainty and updates its assessment of assets-in-place to either \( \{h, 0\} \) or \( \{l, 0\} \) depending on the realization of \( s \). It should be emphasized that there is no information asymmetry between the owner-managers and the market regarding any of these parameters describing the assets-in-place. This characterization of the dynamics of the assets-in-place value allows us to capture the essence of SEBI’s regulatory framework with regard to the issue price of a preferential allotment in a stylized manner. Henceforth, we will refer to the price path dynamics as being under a “high price path” (when \( s = h \)) or under a “low price path” (when \( s = l \)).

3.2 Hidden Value (HV)

The market believes that there could be hidden value (or a lack of it) in the firm, in addition to the value of the assets-in-place. Hidden value takes the form of outcomes \( \{t, 0\} \) with equal probability, where \( t \) itself is a random variable that is uniformly distributed over the range \( \{-H, H\} \). Thus, hidden value can be favorable news or unfavorable news. The random variable \( t \) captures asymmetric information in the context of the model, in a simple fashion. Both the market and the owner-managers are equally uninformed about the value of \( t \) at date \( \tau = -1 \), and hence, there is no information asymmetry on that date. At date \( \tau = 0^- \), owner-managers
privately observe a signal of \( t \), which helps them to make a call on their investment-financing decision.

### 3.3 Investment Opportunity (IO)

At date \( \tau = -1 \), the market becomes aware of a positive NPV investment opportunity that the firm possesses. This investment opportunity requires an investment of \( I \) and yields cash flows \( CF = x, y \) at date \( \tau = +1 \) with equal probability. The market and the owner-managers are symmetrically informed about the nature of the payoffs on the investment opportunity. Since the project has a positive NPV, the implication is that \( I < \frac{1}{2}(x + y) \).

It is important that we clarify our modeling choices about the structure of information. First, one could model the value of assets-in-place (AIP) as simply \( s \), instead of a random binary variable \((s, 0)\). In a similar vein, we could also have defined hidden value (HV) as \( t \) instead of a binary random variable \((t, 0)\), and the cash flows from the project as a non-random quantity, instead of a binary random variable, \((x, y)\). Our information structure is only slightly more complex than the minimum required, but it provides the realistic flavor of postponing uncertainty resolution about cash flows from the asset-in-place (AIP) and the project until the last possible date.

Second, on the terminal date \( \tau = 1 \), the worst realization of \( t \), which is a signal for the hidden value, is \(-H\), and the worst possible realization of the value of the assets-in-place (AIP) is 0. If the firm chooses not to invest in the positive NPV investment opportunity, this worst case scenario could result in negative asset prices. We ensure positive prices in the economy by assuming that the value of the assets-in-place consists of a deterministic part and an uncertain part (given by \( s, 0 \)). The deterministic part is assumed to be sufficiently positive to preclude the possibility of negative asset values.\(^9\)

At date \( \tau = 0^- \), the market sees the realization of \( s \) and then the owner-managers observe a private signal \((t)\) about the hidden value \((HV)\). The main objective of the model is to capture the investment-financing decision of the owner-managers. Owner-managers can choose among the following alternatives: (i) issue equity to outsiders \((OE)\) and invest in the positive NPV opportunity, (ii) issue equity using the rights offering alternative \((RO)\) and invest in the positive NPV opportunity, (iii) issue equity to themselves, using the preferential allotment mechanism \((OM)\) and invest in the positive NPV opportunity, or (iv) reject the project and underinvest

\(^9\)Without loss of generality, we set the deterministic part to be equal to 0 for convenience.
The time-line showing when information is revealed and the choices available is summarized below in Figure 2.

Figure 2: Schematic Description of the Model

Figure 2: Schematic Description of the Model. This figure shows the schedule of events. At date $\tau = -1$, the market becomes aware of a positive NPV investment opportunity that the firm possesses. This investment opportunity requires an investment of $I$ and yields cash flows $CF = x, y$ at date $\tau = +1$ with equal probability. Firm value is made up of value due to assets-in-place ($AIP$), consisting of a deterministic part normalized to 0 and an uncertain part described by an equal-probability binary random variable $(s, 0)$, and a hidden value ($HV$).

3.4 Summary of Key Assumptions

We now summarize the main assumptions made in the model:

1. Firm value is made up of value due to assets-in-place ($AIP$), consisting of a deterministic part normalized to 0 and an uncertain part described by an equal-probability binary random variable $(s, 0)$, and a hidden value ($HV$), which is described by an equal-probability binary variable $(t, 0)$. Owner-managers face a positive NPV investment opportunity, which requires an investment $I$ and throws up cash flows described by an equal-probability binary random

---

10We will later consider the additional alternative of issuing equity to private equity investors as well as owner-managers(PE) and investing in the positive NPV investment opportunity.
variable \((x, y)\). Firms are allowed to raise equity in the form of public issues, rights offerings, or preferential allotments to owner-managers.

2. The issue price in a preferential allotment is subject to regulatory constraints - in essence, preferential allotments can be made at a price \textit{no less than} the maximum of the most recent firm value and the average firm value during the previous period (this assumption captures the essence of the SEBI regulations on the issue price in a preferential allotment).

3. Owner-managers own a fraction, \(\alpha\), of the firm and maximize the liquidation value of their total holdings (as on date \(\tau = +1\)).

4. There is information asymmetry only about the existing assets of the firm and not about the positive NPV investment opportunity. Owner-managers observe a private signal \((t)\), which determines the hidden value associated with the existing assets of the firm.

5. Debt financing is ruled out.

6. The firm has no financial slack and the entire investment in the positive NPV project has to be raised through equity financing. Due to regulatory restrictions, the firm cannot issue stock in excess of the investment in the project.

7. All participants in this economy are risk-neutral. The risk-free rate is normalized to 0 without loss of generality.

8. There are no taxes and transaction costs in the model.

9. There are no agency problems among the owner-managers.

Assumptions #1 and #2 describe the nature of the problem being examined in this model. Assumption #3 is consistent with the assumption in Wu and Wang (2005), but different from the original Myers and Majluf (1984) model, where managers maximize the weighted average of the current and future share value of the firm. The only critical assumption in the above depiction of the model is Assumption #4, which states that there is information asymmetry only about existing assets and not about the investment opportunity. Employing this simpler setup allows us to focus on the key implications of this model, while providing much greater insight into the factors that drive the results of the model. This assumption is relaxed in Appendix 1, where information asymmetry exists about \textit{both} the existing assets and the NPV of the project. We show there that the results developed in this section continue to hold in the more general setup. Assumptions #5-9 are purely for convenience in establishing the results and the model is robust.
to the relaxation of these assumptions. Assumption #6 is made partly for convenience, but also to stay within the spirit of the regulatory constraints on preferential allotments.

Before proceeding further, note that firm value at each point in time depends on the information available to the market at that point in time. Let $V^0 - (s)$ denote the pre-announcement (date $\tau = 0^-$) market value of the firm. This value will be given by the sum of the market value of the assets-in-place ($AIP$), the market expectations of the hidden value ($HV$) and the NPV of the investment opportunity ($IO$), which is equal to $\frac{x+y}{2} - I$. On this date, the market’s expectation of the hidden value ($HV$) is zero. Furthermore, at date $\tau = 0^-$, the expected value of the assets-in-place ($AIP$) is equal to $s/2$. It follows that $V^0 - (s = h) = \frac{h}{2} + \frac{x+y}{2} - I$ and $V^0 - (s = l) = \frac{l}{2} + \frac{x+y}{2} - I$, and in general $V^0 - (s) = \frac{s}{2} + \frac{x+y}{2} - I$. If $V_{-1}$ denotes the market value at time $\tau = -1$, then $V_{-1} = V^0 - (s = h)\frac{1}{2} + V^0 - (s = l)\frac{1}{2} = \frac{h+l}{4} + \frac{x+y}{2} - I$. Note that $V^0 - (s = h) > V_{-1} > V^0 - (s = l)$.

SEBI regulations require that the issue price in a preferential allotment should be at least as high as the higher of the historical average of past prices and the current (most recent) price levels at the time of the preferential allotment. Starting from date $\tau = -1$, prices can either go up ($s = h$) or down ($s = l$). On the high price path, the historical average price would be lower than the most recent price, whereas on the low price path, the historical average price would be greater than the most recent price. Thus, on the high price path, SEBI regulations require that the issue price should be at least as high as the current price. Conversely, on the low price path, SEBI regulations imply that the issue price has to be greater than the historical average price. This means that, when $s = l$, owner-managers who buy shares in a preferential allotment pay an additional premium over and above the current market value. The following proposition and later corollary describe the owner-managers’ decision-making calculus at date $\tau = 0$.

**Proposition 1.** There is no underinvestment in the economy, i.e., all positive NPV projects will be taken up. The owner-managers’ investment-financing decision can be summarized by a threshold cutoff, $\hat{t}(s) = \frac{h-s}{4}$. For all $t < 0$, the firm chooses the outside equity alternative ($OE$), for all $t : 0 < t \leq \hat{t}(s)$, the firm prefers the rights offering alternative ($RO$), and for all $t \geq \hat{t}(s)$, the firm chooses the preferential allotment alternative ($OM$).

Proof: See Appendix 1.

\footnote{It is shown in Appendix 1, Section A.1.1 that this claim holds true in equilibrium, after one accounts for the financing and investment decision of the owner-managers.}
The owner-managers’ financing choice depends on $t$, the signal of hidden value that they privately observe at $\tau = 0^-$. Proposition 1 states that, if $s = h$, i.e., if the price path dynamics is along the “high price path”, the cutoff $\hat{t}(h) = 0$. This implies that owner-managers issue equity to outsiders ($OE$) only if they observe a negative signal ($t < 0$); otherwise they issue equity to themselves ($OM$) through thepreferential allotment mechanism (if $t > 0$). The results of the proposition are intuitive: this situation ($s = h$) corresponds to the classic Myers and Majluf (1984) world, under the additional assumption that insiders are allowed to finance the project. Note that the rights offering alternative ($RO$) is never taken up in this case.

In contrast, when $s = l$, i.e., when the price path dynamics follow the “low price path”, $\hat{t}(l) \equiv \hat{t}(s) > 0$. As in the above case, if the signal is bad ($t < 0$), owner-managers prefer to issue equity to outsiders ($OE$). If the signal is substantially good ($t \geq \hat{t}(l)$), owner-managers prefer to issue equity to themselves ($OM$) (assuming, as we do, that they are not financially constrained). For weakly positive signals ($0 \leq t < \hat{t}(l)$), the intermediate alternative of a rights offering ($RO$) is preferred.

The reason for this asymmetric decision making by owner-managers ($OM$) (with regard to $s = h$ and $s = l$ cases) is the SEBI-mandated regulatory constraint on the issue price in a preferential allotment. SEBI regulations state that the issue price should be greater than the maximum of the most recent valuation and the average valuation over the previous six-month period. When $s = h$, SEBI regulations require the preferential issue to be priced at least as high as the most recent valuation. This requirement ensures that the issue is “fairly priced”. On the other hand, when $s = l$, the preferential issue has to be priced at least as high as the historical average valuation, which, by construction, is always greater than the most recent valuation because prices are declining along the “low price path”. As a result, in the $s = l$ case, owner-managers (as buyers in the preferential allotment) pay a premium over and above the most recent market value of the security. This additional payment causes owner-managers to adopt a more conservative financing policy. In contrast to the $s = h$ case, owner-managers issue equity to themselves ($OM$) only for sufficiently positive signals of $t$ above a strictly positive threshold cutoff value ($\hat{t}(l)$). In the intermediate signal range, the rights offering is the preferred alternative.

To establish the above result formally, it is useful to examine the opportunity gains (costs) faced by owner-managers when opting for each of the four alternatives: $OE$, $RO$, $OM$, and
First, if owner-managers forgo the project (UI alternative), their opportunity loss is $-\alpha NPV = -\alpha\left(\frac{x+y}{2} - I\right)$, noting that owner-managers hold a fraction $\alpha$ of the firm. Now consider the OE alternative. In this case, owner-managers face dilution whenever they observe a good signal of hidden value (i.e., when $t > 0$) because the issue price then reflects a lower firm value than the value based on their private information about the hidden value. Note that the firm value is then understated by an amount equal to $\frac{t}{2}$, given that the hidden value takes the form of $t$ in the good state, and 0 in the bad state (the probability of each state is $\frac{1}{2}$). If the fraction of the firm sold in the outside equity issue is $f^{OE}(s)$, then the original shareholders, as a group, face a dilution loss of $-f^{OE}(s)\frac{t}{2}$. The opportunity loss of the owner-managers is given by $-\alpha f^{OE}(s)\frac{t}{2}$, where $\alpha$ is the proportionate owner-managers’ shareholding. Note that this opportunity loss transforms into an opportunity gain for the owner-managers when $t$ is negative, and the owner-managers will, therefore, prefer outside equity (OE) when observing negative signals of $t$.

Now consider a rights offering (RO), which is conceptually a combination of a preferential allotment (OM) and an outside equity (OE) offering, since the owner-managers participate in the issue, while selling part of the issue to outsiders. When owner-managers observe a good signal ($t \geq 0$), the rights offering imposes both an opportunity gain (they receive a fraction of the shares in a rights offering) as well as a dilution loss (since the remaining fraction of shares is sold to outside equity holders at a discount to the true value). If $f^{RO}(s)$ is the fraction of the firm sold in the rights offering, the opportunity gain of the owner-managers as buyers is $\alpha f^{RO}(s)\frac{t}{2}$. However, as sellers, the owner-managers face an opportunity loss caused by dilution of $\alpha f^{RO}(s)\frac{t}{2}$. These two effects exactly cancel out and the net opportunity gain/loss is zero (this result holds even when $t < 0$.) The intuition for this result is that if the owner-manager subscribes fully to their share, $\alpha$, of the rights offering and maintains their proportionate shareholding of the firm, they will make neither an opportunity gain nor a loss.

Finally, let us consider the preferential allotment (OM) alternative. This case is slightly more complicated because SEBI’s regulatory constraints affect the opportunity gains/losses of the owner-managers. First, we examine the $s = l$ case. As in the case of rights offerings, owner-managers play a dual role - as buyers in the preferential allotment and as (part) owners selling a stake in the firm. However, unlike in the case of rights offerings, these two effects do not offset each other in general. First, owner-managers (as buyers) also face an opportunity gain when $t > 0$ because they buy undervalued shares. If the fraction of shares issued in the preferential
allotment is \( f_{OM}(s = l) \), this opportunity gain is given by \( f_{OM}(s = l) \frac{t}{2} \). Second, owner-managers (as buyers) pay an additional premium due to SEBI’s regulatory constraints, which require the firm to issue shares at the higher historical average price rather than the most recent market price of the firm. This difference can be shown to be equal to \( \frac{(h - l)}{8} \) (see Equation 10, Appendix 1). Thus, the opportunity loss due to this additional premium is given by \( -f_{OM}(s = l) \frac{(h - l)}{8} \). Taken together, the net gain for owner-managers in their role as buyers is equal to \( f_{OM}(s = l) \left[ \frac{t}{2} - \frac{(h - l)}{8} \right] \).

The original shareholders, as a group, lose whatever the buyers gain. Thus, the original shareholders, as a group, lose \( f_{OM}(s = l) \left[ \frac{t}{2} - \frac{(h - l)}{8} \right] \). However, because the owner-managers hold only a fraction \( \alpha \) of the firm, they face only a fraction \( \alpha \) of this cost in their role as owner-managers. Now consider the overall effect on the owner-managers: as buyers they gain \( f_{OM}(s = l) \left[ \frac{t}{2} - \frac{(h - l)}{8} \right] \) but as sellers they lose \( \alpha f_{OM}(s = l) \left[ \frac{t}{2} - \frac{(h - l)}{8} \right] \). The net effect is an opportunity gain (loss, if negative) of \( (1 - \alpha)f_{OM}(s = l) \left[ \frac{t}{2} - \frac{(h - l)}{8} \right] \). Note that the preferential allotment alternative imposes a reverse dilution effect on the owner-managers. An opportunity gain occurs when \( t \) is positive and an opportunity loss when \( t \) is negative. The case when \( s = h \) can be worked out as a special case where SEBI’s regulatory constraints imply that the issue can be priced at the most recent valuation, i.e., there is no additional premium imposed on the issue price. This implies that the opportunity gain is given by \( (1 - \alpha)f_{OM}(s = h) \left[ \frac{t}{2} \right] \).

The opportunity gain (loss) lines for the \( s = h \) case are shown in Figure 3. The outside equity alternative is shown by the downward-sloping line passing through the origin. The rights offering alternative is represented by the \( x \)-axis. The preferential allotment alternative is represented by the upward-sloping line. The \( UI \) alternative is represented by the line parallel to the \( x \)-axis in the lower quadrants. The \( OE(s = h) \) and \( OM(s = h) \) opportunity cost lines intersect exactly at the origin. The V-shaped contour that follows the \( OE \) opportunity gain line for all values of \( t \) below 0 and the \( OM(s = h) \) opportunity cost line for all values of \( t \) greater than 0 describes the optimal investment-financing decision of owner-managers when \( s = h \). For no value of \( t \) would the \( UI \) alternative be considered worthwhile, since the opportunity loss (gain) under other alternatives would be strictly lower (higher). In other words, there will be no underinvestment in the economy. The critical value of \( t \) when the owner-manager switches from the \( OE \) alternative to the \( OM \) alternative is 0, which is the same as the value of \( \tilde{t}(h) = 0 \), as stated in Proposition 1. It can be seen that the \( s = h \) case is simply the Myers and Majluf world where owner-managers face no capital constraints and are allowed to finance projects by investing in the firm’s equity at the prevailing market price. Thus, as in the original Myers-Majluf world, underinvestment is
completely eliminated when preferential allotments to owner-managers are feasible. Note that rights offerings per se can also resolve the underinvestment problem. However, the rights offering alternative is dominated by the preferential allotments alternative (when $t \geq 0$).

The $s = l$ case is shown in Figure 4. The $UI$ alternative is independent of $t$, the $OE$ alternative is a declining linear function of $t$, the $RO$ alternative coincides with the $x$-axis, and the $OM$ alternative is an increasing linear function of $t$.

Figure 3: Owner-Manager’ Opportunity Gains/Costs when $s = h$

This figure shows the owner-managers opportunity gains/costs arising from the following investment-financing decisions: (i) Stock issue to outside equity holders ($OE$), (ii) Preferential allotment of shares to owner-managers ($OM$), (iii) Rights offering to existing equity holders ($RO$), and (iv) Under-investment alternative ($UI$). The opportunity gains/costs are a function of the owner-managers private information about the hidden value in the firm ($t$). For a given realization of $t$, one among the four alternatives dominates the other three alternatives. The bold face line-segments depict how the dominating alternative varies with hidden value($t$).
SEBI pricing regulations, which apply only in the OM alternative, imply that the y-intercept of the preferential allotment alternative is equal to $-\frac{(h-l)}{8}$, the additional premium paid by owner-managers. The bold-faced piece-wise linear portion of the graph represents the optimal financing choices as a function of $t$. It can be seen that the $UI$ alternative is dominated by one of the other alternatives at each and every value of $t$. In other words, in this case too, there will be no underinvestment in the economy. For weak signals of $t$, outside equity ($OE$) is optimal, for intermediate values of $t$ the rights offering ($RO$) alternative is optimal, and for good signals of $t$, the preferential allotment alternative ($OM$) is optimal. The range of $t$ where the rights offering alternative dominates is given by $t \in (0, \tilde{t})$, where $\tilde{t}$ is the point at which the opportunity cost line for the preferential allotment alternative intersects the $x$-axis. Setting $\alpha f^{OM}(s = l)[\frac{1}{2} - \frac{(h-l)}{8}] = 0$, we get $\tilde{t} = \frac{h-l}{4}$, which is exactly the same as $\hat{t}(s) = \frac{h-s}{4}$, as discussed in Proposition 1. Note that the rights offering financing alternative dominates both the outside equity offering and the preferential allotment for all $t \in (0, \hat{t}(s))$.

The optimal investment-financing decision of the owner-managers is slightly different in the $s = h$ case than in the $s = l$ case. In the former case, the rights offering ($RO$) alternative is sub-optimal, but in the latter case it serves as the optimal alternative for intermediate values of $t$, due to regulatory constraints. Otherwise, the financing strategy is similar in both cases; for weak signals outside equity ($OE$) is optimal, and for good signals preferential allotment ($OM$) is optimal. However, note that owner-managers use a more conservative cutoff when opting for a preferential allotment in the $s = l$ case, in order to recover the additional premium imposed by SEBI regulations on the issue price. Therefore, the signal value has to be sufficiently high to trigger a preferential allotment in the $s = l$ case.

To summarize, the underinvestment situation that arises in the Myers and Majluf (1984) world is eliminated when preferential allotment to insiders $OM$ and rights offering $RO$ are allowed.\footnote{If the project has a negative NPV, our model implies that, for extremely good (bad) news about the hidden value, a preferential allotment to owner-managers (outside equity) will be used. Thus, overinvestment will occur. For intermediate realizations of the hidden value, the project will not be taken up (underinvestment). This fact can easily be verified in graphical terms by considering a negative NPV project in Figure 4. The opportunity cost of the $UI$ alternative will then lie above (and parallel) to the $x$-axis. The optimal financing plan will be similar to that shown in Figure 4, except that the underinvestment will be optimal for intermediate ranges of $t$. Because preferential allotments to owner-managers arise only when the good news about the hidden value more than offsets the bad news implicit in the negative NPV project, the information content of a preferential allotment to owner-managers will be positive even when the project has a negative NPV. For extremely adverse news about the hidden value, the negative NPV project may be taken up with outside equity financing. Outsiders will still be subscribing to an equity issue in that case, because the issue price is always “fair,” conditional on their information set. This will result in socially sub-optimal overinvestment. Finally, there will be a positive reaction...}
The overall intuition behind this result is as follows. When insiders see “good” information, they are reluctant to issue equity to outsiders due to the dilution of the original shareholders’ wealth, because of the information asymmetry between insiders and outsiders. In this model, the information asymmetry-driven “dilution” problem is completely resolved because shares will be issued either fully (through a preferential allotment) or partially (through a rights offering) to informed insiders rather than to uninformed outsiders when the information is “good”. The rights offering alternative is useful for marginally good news that is insufficient to overwhelm the additional costs imposed by the SEBI regulatory constraints. When the information is “bad”, shares will be issued to outsiders, who are always willing to buy them because they are issued at the fair value (SEBI regulations apply only to preferential allotments). Of course, firms may be interested in selling even more equity than they require to fund the project, which is not permitted by assumption.

Figure 4: Owner-Manager Opportunity Gains/Costs when \( s = 1 \)

\[
\text{Opportunity Cost} = \begin{cases} 
\alpha f^{OE}(s = 1) \frac{t}{2} & \text{Outside Equity (OE), } s = 1 \\
0 & \text{Rights Offering (RO), } s = 1 \\
(1 - \alpha) f^{PA}(s = 1) \left[ \frac{h-l}{s} + \frac{t}{2} \right] & \text{Preferential Allotment (OM), } s = 1 \\
-\alpha NPV & \text{No Investment (UI)}
\end{cases}
\]

This figure shows the owner-managers\(^{\dagger}\) oppor
tunity gains/costs when \( s = 1 \). This figure shows the owner-managers to underinvest because the pre-announcement price reflects the negative NPV investment opportunity. The general case of negative NPV investment opportunities is discussed in detail in Cooney and Kalay (1993).
opportunity gains/costs arising from the following investment-financing decisions: (i) Stock issue to outside equity holders (OE), (ii) Preferential allotment of shares to owner-managers (OM), (iii) Rights offering to existing equity holders (RO), and (iv) Under-investment alternative. The opportunity gains/costs are a function of the owner-managers' private information about the hidden value in the firm \((t)\). For a given realization of hidden value, one among the four alternatives dominates the other three alternatives. The bold face line-segments depict how the dominating alternative varies with hidden value \((t)\).

To summarize, the underinvestment situation that arises in the Myers and Majluf (1984) world is eliminated when preferential allotment to insiders (OM) and rights offering (RO) are allowed.\(^{13}\) The overall intuition behind this result is as follows. When insiders see “good” information, they are reluctant to issue equity to outsiders due to the dilution of the original shareholders’ wealth, because of the information asymmetry between insiders and outsiders. In this model, the information asymmetry-driven “dilution” problem is completely resolved because shares will be issued either fully (through a preferential allotment) or partially (through a rights offering) to informed insiders rather than to uninformed outsiders when the information is “good”. The rights offering alternative is useful for marginally good news that is insufficient to overwhelm the additional costs imposed by the SEBI regulatory constraints. When the information is “bad”, shares will be issued to outsiders, who are always willing to buy them because they are issued at the fair value (the SEBI regulations modelled above apply only to preferential allotments). Of course, in this case, firms may be interested in selling even more equity than they require to fund the project, which is not permitted by assumption.

3.5 Private Equity Placements

In this section, we introduce the possibility of private equity players participating in a preferential

\(^{13}\)If the project has a negative NPV, our model implies that, for extremely good (bad) news about the hidden value, a preferential allotment to owner-managers (outside equity) will be used. Thus, overinvestment will occur. For intermediate realizations of the hidden value, the project will not be taken up (underinvestment). This fact can easily be verified in graphical terms by considering a negative NPV project in Figure 4. The opportunity cost of the \(UI\) alternative will then lie above (and parallel) to the \(x\)-axis. The optimal financing plan will be similar to that shown in Figure 4, except that the underinvestment will be optimal for intermediate ranges of \(t\). Because preferential allotments to owner-managers arise only when the good news about the hidden value more than offsets the bad news implicit in the negative NPV project, the information content of a preferential allotment to owner-managers will be positive even when the project has a negative NPV. For extremely adverse news about the hidden value, the negative NPV project may be taken up with outside equity financing. Outsiders will still be subscribing to an equity issue in that case, because the issue price is always “fair,” conditional on their information set. This will result in socially sub-optimal overinvestment. Finally, there will be a positive reaction to underinvestment because the pre-announcement price reflects the negative NPV investment opportunity. The general case of negative NPV investment opportunities is discussed in detail in Cooney and Kalay (1993).
allotment. We refer to such preferential allotments as OM-PE to consider the general case of financing by a combination of owner-managers and private equity investors. This possibility is worth considering only if owner-managers are financially constrained and cannot fully subscribe to a stock issue entirely on their own (the OM alternative). Clearly, if owner-managers have sufficient capital, they will prefer to issue all new shares to themselves rather than sharing the benefits with private equity investors, especially when there is a strong positive signal about the hidden value. Hence, the OM-PE alternative is dominated by the OM alternative whenever the latter is feasible. In that case, our analysis in the previous section would have prevailed even if the private equity alternative (OM-PE) had been allowed.

Thus, in our model, the role of private equity arises only in the context of personal financial constraints faced by owner-managers. In general, other factors, e.g., managerial expertise or strategic inputs, might induce an owner-manager to bring private equity players into a financing arrangement. However, our model is concerned with the financing choices that arise even in the absence of other positive benefits, and we focus on the capital constraints of the owner-managers as the driving force behind private equity participation.

When owner-managers obtain good signals about the hidden value \((t)\) but are financially constrained, they will attempt to convince outside investors of the hidden value in the firm. In this regard, it is probably easier to convey private information to a private equity player than to a diffuse set of public shareholders. Clearly, the cost of negotiating a bilateral agreement with a private equity group would be lower than that in an outside equity issue. However, convincing a private equity investor would still be a costly exercise. As argued in Hertzel and Smith (1997), the firm and its owners would incur dead-weight costs of certification in such a case. Instead of modeling the subtleties of negotiation costs, we employ the parsimonious assumption that owner-managers can perfectly communicate their private information (about \(t\)) to private equity investors, i.e., private equity investors have the same information as insiders. Our assumption of zero certification costs may seem extreme; however, as we shall see, the qualitative nature of our conclusions will survive richer assumptions about such costs.

The capital resource constraints of owner-managers may be mild or extreme. Suppose we let \(R\) denote the capital available to owner-managers, and \(\gamma\) the ratio of resources \((R)\) to the investment required for the positive NPV project \((I)\). The ratio, \(\gamma = \frac{R}{I}\), captures the extent of the capital constraints of the owner-managers. If \(\gamma \geq 1\), the owner-managers face no capital
constraints and the project can be entirely funded by them in those states of the world in which they wish to do so, i.e., when \( t \) is high. If \( \alpha \leq \gamma < 1 \) (recall, \( \alpha \) is the owners’ shareholding), the capital constraints are mild in the sense that the owner-managers have enough resources to participate in a rights offering \((RO)\), but not enough to participate in a preferential allotment kept entirely to themselves \((OM)\). On the other hand, if \( \gamma < \alpha \), the owner-managers can no longer participate even in a rights offering let alone a private placement to themselves. However, in both these cases, the owner-managers can take recourse to partial funding by private equity investors to cover the shortage in funds.

Consider the case of mild capital constraints, i.e., when \( \alpha \leq \gamma < 1 \). Similar to the opportunity gains expression for owner-managers \((OM)\), we can show that the opportunity gain (loss, if negative) of a preferential allotment to a combination of owner-managers and private equity players \((OM-PE)\) is given by \( (\gamma - \alpha) f_{OM-PE}(s) \left[ t - \frac{1}{2} \left( h - s \right) \right] \), \( s = h, l \), where \( f_{OM-PE}(s) \) is the fraction of the shares sold to owner-managers in the combined \(OM-PE\) private placement. Note that the expression here is similar to that for the opportunity gain/loss in the case of the pure \(OM\) alternative. The key difference is that the term \( (1 - \alpha) \) in the \(OM\) case has been replaced by the term \( (\gamma - \alpha) \). This can be explained as follows. As discussed earlier, preferential allotments to owner-managers reflect a reverse dilution effect. An opportunity gain occurs when \( t \) is positive and an opportunity loss when \( t \) is negative. In the combination alternative, \(OM-PE\), the owner-managers share the reverse dilution benefit with the private equity players, and their net benefit is reduced from \( (1 - \alpha) \) to \( (\gamma - \alpha) \). As \( \gamma \) approaches 1, the capital constraints become less severe and the \(OM-PE\) alternative converges to the \(OM\) alternative. When \( \gamma = 1 \), i.e., when \( R = I \), the owner-managers have enough capital to subscribe to the preferential allotment by themselves, and the opportunity gains expression converges to the same one as in the pure \(OM\) case.

The case when \( \gamma \geq \alpha \) is just a generalization of the opportunity gain/loss in the \(OM\) case to account for partial funding by the owner-managers. Note that the point of intersection of the opportunity gains line with the \(x\)-axis is the same for both the \(OM-PE\) alternative and the \(OM\) alternative. The opportunity gains expression for \(OM-PE\) is virtually the same as for the \(OM\) alternative, except that the slope of the line is less steep because \( \gamma < 1 \).14

---

14 Another difference is that the fraction of the firm sold to the owner-managers, \( f_{OM-PE}(s) \), will be strictly less than the fraction of shares sold in the case of the \(OM\) alternative. This factor also contributes to the reduction in the slope.
Now, consider visualizing the $OM-PE$ opportunity gains line that was depicted in Figure 3. We can see that the $OM$ alternative will dominate the $OM-PE$ alternative over the relevant range of $t : t > t(s)$, because its opportunity gains line has a greater slope due to the fact that $\gamma < 1$. This implies that the $OM-PE$ alternative is irrelevant when the owner-managers face no capital constraints. Second, consider the case where the owner-managers face mild capital constraints such that $\gamma \geq \alpha$. The $OM$ alternative is no longer feasible. This alternative will be replaced by the $OM-PE$ alternative, which has a similar opportunity gains line. The optimal financing policy will be exactly the same as shown in Figure 3 ($s = h$) and Figure 4 ($s = l$), except that the $OM-PE$ alternative replaces the $OM$ alternative. Outside equity ($OE$) will be used when $t < 0$, rights offerings ($RO$) will be employed for $0 \leq t < t(s)$, and the owner-manager private equity combination ($OM-PE$) will be used for all $t > t(s)$. Importantly, as in the case of no capital constraints, there is no underinvestment.

The more intriguing case is the third case, where $\gamma < \alpha$. Now, the owner-managers are severely capital-constrained and cannot participate in either a rights offering or a pure preferential allotment of shares to themselves. The opportunity gains for the owner-manager private equity combination will still be given by $(\gamma - \alpha)f^{OM-PE}(s)[t - \frac{(h-s)}{8}]$. However, since $\gamma < \alpha$, the slope of the opportunity gains line will be negative, as can be seen in Figure 5 (for the case of $s = h$) and Figure 6 (for the case of $s = l$). The opportunity gains line of the $OM-PE$ alternative is similar to that of the outside equity ($OE$) opportunity gains line. This follows because the owner-managers are capturing very little of the reverse dilution benefits; most of them are going to the outside private equity players. On the other hand, because of their ownership stake ($\alpha$), the owner-managers face costs that are greater than the reverse dilution benefits when they purchase undervalued shares. The net effect is that the private equity alternative becomes similar to the outside equity alternative, except that, in the latter case, the outside investors are unaware of the private signal.

Consider the opportunity gains in the case where $s = h$, as shown in Figure 5. The $OE$ and $UI$ opportunity cost lines are the same as in the earlier figures. The $OM-PE$ alternative is evaluated as follows. First, because $\gamma \geq 0$, $\gamma - \alpha \geq -\alpha$. Further, the fraction of the firm sold to private equity investors reflects the higher valuation they see (as compared to outside equity investors who are uniformed about $t$). This implies that $f^{OM-PE}(s = h) < f^{OE}(s = h)$. Taken together, these inequalities imply that the opportunity cost line for the $OM-PE$ alternative is flatter than
the opportunity cost line for the OE alternative. The optimal investment-financing decision is captured by the bold-faced line in Figure 5. For \( t < 0 \) OE dominates, for \( 0 \leq t \leq t^{PE-UI}(s = h) \) OM-PE dominates, and for \( t > t^{PE-UI}(s = h) \) the firm underinvests (UI). This result is essentially the same as in Myers and Majluf (1984), except that the OM-PE alternative replaces the OE alternative for intermediate values of \( t \).

Now consider the opportunity gains in the case where \( s = l \), as shown in Figure 6. The net opportunity gains from a private equity issue are given by \( (\gamma - \alpha)f^{OM-PE}(s = l)[t - \frac{h-l}{2}] \). The opportunity cost line for the OM-PE alternative is similar to that in the \( s = h \) case, except that it has shifted to the right by an amount \( \frac{h-l}{4} \), reflecting the additional premium due to the SEBI regulatory constraints. The conclusions, however, remain qualitatively similar: for \( t < 0 \) OE dominates, for \( 0 \leq t \leq t^{PE-UI}(s = l) \) OM-PE dominates, and for \( t > t^{PE-UI}(s = l) \) the firm underinvests (UI).

**Figure 5: Owner-Manager’s Opportunity Gains/Costs when \( s = h \) (Owner-managers face Severe Capital Constraints)**

Figure 5: Owner-Manager's Opportunity gains/costs when \( s = h \) and when they face severe capital constraints. This figure shows the owner-managers opportunity gains/costs arising from the following investment-
financing decisions when owner-manager faces severe capital constraints: (i) Stock issue to outside equity holders (OE), (ii) Preferential allotments to owner-managers and private equity (OM−PE) and (iii) Under-investment (UI) alternative. The opportunity gains/costs are a function of the owner-managers private information about the hidden value in the firm \((t)\). For a given realization of hidden value, one among the four alternatives dominates the other three alternatives. The bold face line-segments depict how the dominating alternative varies with hidden value \((t)\).

Our analysis has established that the private equity \(OM-PE\) and rights offering \(RO\) alternatives will be pursued, if at all, only for intermediate values of \(t\). We have assumed here that there are no dead weight costs of certification by the private equity investors, either through a lower issue price or other fees. Even if we relax this assumption, the general conclusion that the \(OM-PE\) and the \(RO\) alternatives would be employed for intermediate values of \(t\) survives.

**Figure 6: Opportunity Gains/Costs when \(s = 1\) (Owner-Managers face Severe Capital Constraints)**

**Figure 6: Owner-Manager’s opportunity gains/costs when \(s = 1\) and when they face severe capital**
This figure shows the owner-managers opportunity gains/costs arising from the following investment-financing decisions when owner-manager faces severe capital constraints: (i) Stock issue to outside equity holders (OE), (ii) Preferential allotments to owner-managers and private equity (OM – PE) and (iii) Under-investment (UI) alternative. The opportunity gains/costs are a function of the owner-managers private information about the hidden value in the firm \(t\). For a given realization of hidden value, one among the four alternatives dominates the other three alternatives. The bold face line-segments depict how the dominating alternative varies with hidden value \(t\).

This can be seen by inspecting Figures 5 and 6 and recognizing that the intercept of the OM-PE opportunity cost line will change due to certification costs, thereby only affecting the range of \(t\) over which the OM-PE or RO alternative dominates. Depending on the capital constraints of the owner-managers, extremely good signals of \(t\) will be associated with preferential allotments, possibly with private equity investors (mild capital constraints), or underinvestment (severe capital constraints). Extremely bad signals, \(t\), will always be associated with outside equity issues. Intermediate values of \(t\) will be associated with a rights offering (mild capital constraints) or private equity (severe capital constraints).

The private equity alternative will compete with the rights offering alternative only in the case of mild capital constraints \((\gamma \geq \alpha)\) and when \(s = l\). The choice between private equity and a rights offering is determined by the dead weight costs of certification and the additional premium due to SEBI-imposed regulatory constraints. As the cost of certification increases, the rights offering alternative becomes more attractive and preferable to the private equity alternative. Recently, SEBI has mandated that rights offerings should also adhere to the issue price constraints imposed on preferential allotments. This change in the rules makes the rights offering a less attractive alternative because owner-managers face higher costs in a rights offering than they would otherwise. In the context of the opportunity gain (loss) figures, this puts the RO alternative below (and parallel to) the \(x\)-axis. However, for sufficiently high values of \(t\), the private equity alternative will still be preferred. If the capital constraints are severe, a rights...
offering will not be feasible, and private equity will be preferred for intermediate signals, \( t \).

To summarize, mild capital constraints leave our results in the previous section intact. Our model is mainly motivated by the desire to understand the optimal investment-financing decisions of family-promoted businesses in emerging markets. Owner-managers of family-controlled firms often have deep pockets and face less severe capital constraints than do public corporations run by professional managers. Our model unambiguously shows that the underinvestment problem can be resolved by allowing preferential allotments to owner-managers, exclusively or in combination with private equity players. While this conclusion is intuitively reasonable, our model exploits the institutional peculiarities of an emerging market environment such as India to derive empirically testable implications associated with reactions to announcements of preferential allotments. This rigorous framework allows us to examine the importance of information asymmetry in explaining the announcement effects of preferential allotments. When capital constraints are severe, the situation is similar to that in Myers and Majluf, because in their model owner-managers are assumed to be risk averse, which is mirrored by capital constraints in our model.

3.6 Empirical Implications

We next explore the comparative statics properties of the critical threshold \( \hat{t}(s) \), which determines the cutoff beyond which the owner-managers prefer the preferential allotment alternative.

Corollary 1.

i. The critical threshold cutoff, \( \hat{t}(s) \), which triggers the preferential allotment to owner-managers, has the following properties:

\[
\hat{t}(h) = 0 < \hat{t}(l) = \frac{h - l}{4}, \quad \frac{\partial \hat{t}(l)}{\partial (h - l)} > 0, \quad \frac{\partial \hat{t}(l)}{\partial \alpha} = 0
\]  

\[ \tag{1} \]

ii. The announcement period reaction associated with a preferential allotment to owner-managers, \( \Delta P(s) \), is greater than 0:

\[
\Delta P(s) = \frac{[\hat{t}(s) + H]}{4} = \frac{1}{16} (h - s) + \frac{H}{4} > 0, \quad s = l, h
\]  

\[ \tag{2} \]
iii. The announcement period reaction associated with a preferential allotment to owner-managers is inversely related to the price path dynamics \((s = l, h)\), positively related to the degree of information asymmetry about hidden value \((t)\), and unrelated to the owner-managers shareholdings \((\alpha)\). Conditional on \((s = l)\), the announcement period returns are positively related to the degree of uncertainty in the value of assets-in-place \((hl)\).

\[
\Delta P(s = h) < \Delta P(s = l), \quad \frac{\partial \Delta P(s)}{\partial H} > 0, \quad \frac{\partial \Delta P(s)}{\partial \alpha} = 0, \quad \frac{\partial \Delta P(s = l)}{\partial (h - l)} > 0 \quad (3)
\]

iv. The announcement period reaction associated with a preferential allotment to private equity investors is lower than the announcement period reaction associated with a preferential allotment to the owner-managers.

\[
\Delta P|_{PrivateEquity} < \Delta P|_{Owner-managers} \quad (4)
\]

Proof: See Appendix 1.

Corollary 1 (i) presents a few properties of the critical threshold cutoff, \(\hat{t}(s)\). As discussed earlier, the cutoff is exactly equal to 0 for \(s = h\), but strictly greater than 0 for \(s = l\). The relationship with \(h - l\) and \(\alpha\) can be seen immediately. Corollary 1 (ii) discusses the model’s implications about the announcement period effects of preferential allotments to owner-managers.

Upon the announcement of a preferential allotment to owner-managers, the market infers that the owner-managers must have seen a private signal, \(t > \hat{t}(s)\). Since the hidden value is given by the outcomes \((t, 0)\), where each of the outcomes is equally likely, the unconditional expectation of the hidden value is \(\frac{t}{2}\). It follows that the expectation of the hidden value, conditional on a preferential allotment, is equal to \(E[\frac{t}{2} | t > \hat{t}(s)]\), which is equal to \(\frac{\hat{t}(s) + H}{4}\), given that \(t\) arises from a uniform distribution over the interval \((-H, H)\). Corollary 1 (ii) states the announcement period returns for preferential allotments to owner-managers in closed form after substituting for \(\hat{t}(s)\).

Note that the announcement period return is positive for preferential allotments. The results in Corollary 1 (iii) follow immediately from the above results. Finally, since preferential allotments to private equity investors are made only for intermediate signals \(t\) and preferential allotments to owner-managers are made for extremely good signals \(t\), it follows that the announcement period reaction of the former will be less than that of the latter, as stated in Corollary 1 (iv).\(^8\)

\(^8\)The focus of our study is on preferential allotments, but the model also provides empirically testable implications for outside equity issues. The model suggests that the average inferred news about \(t\), conditional on the
7 provides a schematic summary of the models predictions about announcement period returns for the case when owner-managers face no capital constraints, the relevant case for our empirical analysis of preferential allotments in emerging markets.

Figure 7: Owner-Managers’ Investment-Financing Decisions (with no capital constraints) and Announcement Period Returns. This figure summarizes the investment financing decision of the owner-managers for the two price paths (s = h and s = l). The investment financing decision depends on the hidden value (t). The issue price is based on SEBI guidelines for preferential allotments and ordinary equity issues. In the last column, the announcement period reaction associated with each of the investment-financing decisions is shown.

3.7 Manipulation

From an economic growth perspective, preferential allotments to owner-managers are a positive institutional arrangement.\(^{19}\) However, the price at which these shares are issued to insiders is critical because managers may have incentives to manipulate share prices (in order to issues shares to themselves at a discount to their true value). Mechanisms such as the SEBI-mandated issue price regulations try to reduce the potential benefits of manipulation, since owner-managers are forced to issue shares at a historical average price rather than at the most recent valuation (as would be the case in an outside equity issue). This feature of the SEBI regulations allows the market to preserve the potential social benefits of preferential allotments without causing an

\(^{19}\)The discussion here does not deal with possible “tunneling” activity where owner-managers siphon resources from the new project. See Bertrand et al. (2002), for an analysis.
adverse effect on the minority shareholders’ welfare. The fact that SEBI has put such a regulation in place indicates that manipulation is a serious concern for regulators. In this subsection, we formulate a generalized version of the model that accounts for the manipulation incentives of owner-managers and derives testable empirical implications in their presence.\(^{20}\)

Below we sketch a simple formulation of manipulation in the context of our basic model, where owner-managers can bring down the price level per share (before announcing the preferential allotment) by an amount \(w\).\(^{21}\) Owner-managers benefit from manipulation because they are able to issue shares at a lower price (by an amount equal to \(w\)) than otherwise. Obviously, owner-managers would want to increase \(w\) by as much as possible. However, it is reasonable to assume that manipulation is a costly exercise that may involve dead weight (fixed) costs and increasing marginal costs, as suggested in the market microstructure literature (see Kyle (1985) and other studies on the price impact of trades), and, because manipulation is an illegal activity, direct penalty costs as well as reputation costs. These costs are likely to be increasing in the degree of manipulation and it is safe to assume that manipulation will be bounded from above due to such costs. Even within this upper limit - a breakeven level of manipulation, beyond which the costs of manipulation exceed the benefits - owner-managers may prefer to choose an interior level of manipulation \((w^*)\) depending on the marginal costs and benefits of manipulation. For the purposes of our paper, the exact nature of such an optimization exercise is of secondary importance. Therefore, we generalize our model under the assumption that the owner-managers choose a level of manipulation given by \(w^*\), where \(w^*\) has been determined through an exogenously specified optimization exercise.\(^{22}\)

The effect of manipulation on our base case model (without resource constraints on owner-

\(^{20}\)In this paper, our objective of empirically testing the model on Indian securities market data can be achieved by taking the SEBI pricing rules as exogenously given. In general, from a policy perspective, it may be useful to develop a model of optimal regulation where the issue pricing rules in preferential allotments are endogenously derived.

\(^{21}\)Models of manipulation can be classified into trade-based manipulation models [Allen and Gorton (1992), Brunnermeier (2000)], information-based manipulation models [Benabou and Laroque (1992)] and action-based manipulation models [Bagnoli and Lipman (1996)]. In trade-based manipulation models, prices are manipulated using sophisticated trading strategies. In information-based manipulation models, prices are manipulated by the strategic release of news about a firm. Finally, in action-based manipulation models, profitable trading positions are taken up just prior to a critical action that is initiated by a related party (for instance, a takeover bid may be announced). In the setting of our model, the type of manipulation is not directly relevant; all that matters is that the manipulation causes the price to move the direction desired by the owner-managers, and away from its fundamental value.

\(^{22}\)We discuss the nature of such an optimization exercise in Appendix 1.
managers) can be seen in the context of Figure 4. The slopes of the opportunity cost lines for $OE$ and $OM$ ($s = l$) change as the fraction of shares sold increases, due to the lower (manipulated) issue price. The net result is that both lines become steeper - the $OE$ opportunity cost line rotates clockwise and the $OM$ opportunity cost line rotates counter-clockwise. However, the important point to note is that the $OM$ opportunity cost will continue to intersect the $x$-axis at the same cutoff, $\hat{t}(s) = \frac{h-s}{4}$. This can be seen from the expression for the opportunity cost of the $OM$ alternative, given by $(1 - \alpha)\hat{f}^{OM}(s = l)[\frac{t}{2} - \frac{(h-l)}{8}]$. As the level of manipulation ($w^*$) increases, $\hat{f}^{OM}$ increases (reflecting the fact that a greater number of shares have to be sold at the lower manipulated price). However, the $x$-intercept is driven by the term in the square brackets, $[\frac{t}{2} - \frac{(h-l)}{8}]$, which yields the same cutoff value of $\hat{t}(s) = \frac{h-s}{4}$. The key implication is that the announcement period reaction to preferential allotments would remain at the expected level stated in Corollary 1 (ii), and would therefore be independent of the degree of manipulation in this information asymmetry-based model. This result provides the basis for a testable empirical implications of the model, as will be discussed below.

3.8 Testable Hypotheses

We formulate the following hypotheses based on our model and the extant literature. Hypotheses H.1-H.5 are based on the empirical implications arising from the model and we refer to these collectively as the Undervaluation Hypotheses.

3.7.1 Hypotheses Based on the Model

H.1 The announcement period price reaction to preferential allotments should be positive.

H.2 The announcement period price reaction should be more positive if the preferential allotment occurs after a low price path ($s = l$), than if it occurs after a high price path ($s = h$).

H.3 The announcement period reaction should be positively related to the volatility of returns.

H.4 The average announcement period reaction should be unrelated to the owner-managers’ pre-announcement shareholdings ($\alpha$).

H.5 The announcement price reaction to preferential allotments to private equity investors should be lower than the reaction to preferential allotments to owner-managers.

\[23\] The case with resource constraints, when raising funds from private equity may be optimal, can be analyzed in a similar fashion, with appropriate modifications.
Proposition 1 shows that the manager’s choice of financing depends on the signal of the hidden value ($t$), and whether $s = h$ or $s = l$. The owner-managers favor preferential allotment for positive $t$ when $s = h$, and for sufficiently positive $t$ when $s = l$. Hypothesis H.1 states that announcement period reactions, on average, should be positive for preferential allotments. It follows from Corollary 1 (ii).

Hypothesis H.2 discusses the impact of the price path dynamics. When $s = l$, the SEBI-imposed issue price formula is based on the historical average price, which is greater than the most recent market valuation. The issue price reflects an additional premium, and the owner-managers become more cautious about preferential allotments when $s = l$ than when $s = h$. They will choose a higher cutoff, $\hat{t}(s)$, for the $s = l$ case. The announcement period reaction to preferential allotments when $s = l$ will, therefore, be greater than when $s = h$, because preferential allotments in the former case occur more selectively (i.e., for higher signals of $t$).

Hypothesis H.3 also follows directly from Corollary 1 (iii). First, the announcement period reaction is positively related to $H$, which captures the magnitude of information asymmetry about the hidden value ($HV$). Further, the announcement period reaction is positively related to $(h - l)$, which captures the uncertainty in the value of the assets-in-place ($AIP$). Now, since the volatility of returns is positively related to uncertainty about both the hidden value and the assets-in-place, it follows that the announcement period return should be increasing in the volatility of returns (Hypothesis H.3). In terms of intuition, more volatile stocks imply a greater amount of information uncertainty ($H$), as well as a higher additional premium (which depends on $(h - l)$, due to the SEBI-mandated issue-pricing restrictions). As can been seen from the expression for the announcement period returns, it is increasing in $H$ and $h - l$. Hypothesis H.4 and Hypothesis H.5 follow from Corollary 1 (iii).

Hypothesis H.5 indicates that the announcement period reaction of preferential allotments to owner-managers should be greater than that of preferential allotments to private equity investors. This hypothesis follows from Corollary 1(iv). In contrast, according to the Monitoring Hypothesis, since private equity players are active shareholders, the announcement period reaction should be higher. Similarly, the Certification Hypothesis argues that private equity players often possess superior information about the prospects of a firm and their participation is a signal of value. Thus the Certification Hypothesis also argues that the announcement period reaction of preferential allotments to private equity investors should be higher.

34
Our empirical tests are based on a set of preferential allotments issued to all types of buyers (not just owner-managers, but also to private equity firms, banks and financial institutions) because our basic model is applicable in all these cases. Some of the above predictions are unique to our model (Hypotheses H.2, H.3, H.4, and H.5), the remaining predictions can also arise in the context of alternative hypotheses. However, Hypothesis H.1 (positive announcement period returns) is also implied by the Monitoring Hypothesis (private equity players provide better monitoring) as well as the Certification Hypothesis (the presence of private equity is a credible signal of hidden value). Note also that exactly the converse of Hypothesis H.1 is implied by the Entrenchment Hypothesis, which suggests that preferential allotments should be associated with negative announcement period returns because of managerial self-dealing.

Hypothesis H.4 applies is unique to our model. It states that announcement period reaction should be unrelated to owner-manager shareholdings. On the other hand, the Certification Hypothesis and the Monitoring Hypothesis suggest that announcement period returns should be positively related to owner-manager shareholdings because the value of certification and monitoring is higher when the manager holds a higher ownership stake. In contrast, the Entrenchment Hypothesis suggests that greater insider ownership is associated with greater managerial self-dealing and announcement period reaction should therefore be decreasing in insider ownership. Empirical tests of the competing hypotheses can, therefore, help us understand the relative validity of the various alternative hypotheses in explaining preferential allotments in the Indian capital markets.

3.7.2 Manipulation Revelation Hypotheses

Manipulation is an important issue in the context of preferential allotments because it could, by itself, suggest empirical implications similar to those suggested by the information asymmetry explanation proposed in this paper. The announcement of a preferential allotment reveals to the market that the owner-managers might have been manipulating the prices downward in the prior period. The market would then correct itself with a positive adjustment, i.e., the announcement period reaction would be positive. Thus, positive announcement effects can arise in the context of preferential allotments to owner-managers due to a fear of manipulation by the latter. We refer to this effect as the Manipulation Revelation Hypothesis. It suggests that, in a world of manipulation, preferential allotments should be associated with positive announcement period return.
returns. This effect would arise even without explicit information asymmetry about the hidden value of the assets, because owner-managers can gain just by buying their stocks at depressed prices. A key implication of the Manipulation Revelation Hypothesis is that announcement period returns are increasing in the proxies for manipulation.

In contrast, as discussed in the previous section, our information asymmetry-based model, after explicitly accounting for manipulation, concludes that announcement period returns would be independent of the proxies for manipulation. Thus, we can empirically establish whether the data support the Manipulation Revelation Hypothesis or the Undervaluation Hypothesis (after accounting for manipulation possibilities). Below, we state the predictions of the Manipulation Revelation Hypothesis. Hypotheses H.6 and H.7 are useful because they present testable propositions that arise only in the context of the Manipulation Revelation Hypothesis, and not in the context of the Undervaluation Hypothesis of the model discussed in this article.

**H.6** On average, the announcement period reaction should be increasing in the illiquidity of the firm’s stock.

**H.7** On average, the announcement period price reaction should be positively (negatively) related to the abnormal returns (abnormal volume) experienced during the six-months prior to the announcement date.

Hypothesis H.6 follows because illiquidity reduces the costs of manipulating asset prices (market prices move much more in the direction favorable to the owner-managers for a given amount of investment in manipulation). In the case of illiquid stocks, manipulation is easier and owner-managers will have greater incentives to manipulate prices, since they will have a greater “bang for the buck” for the resources they employ in manipulation. As a result, the abnormal returns will be higher because the market will infer the worst upon the announcement of a preferential allotment to owner-managers. As stated in Hypothesis H.6, the announcement period reaction should be increasing in the illiquidity of the stock.

Hypothesis H.7 is based on the same logic, except that it uses more direct proxies for manipulation. Two alternative empirical proxies for manipulation are the abnormal volume and the abnormal return in the six-month period prior to the announcement date. If manipulation (in the period prior to the announcement) causes a depressed stock price, then it will result in a negative (or lower) abnormal return during this period than in a world without manipulation. In addition,
an indirect indication of manipulation is the abnormal trading volume in the six months prior to the announcement. Hence, in the presence of manipulation (as measured by a lower abnormal return or a higher abnormal volume in the six-month period prior to the announcement date), the announcement period return will be lower than otherwise. In other words, the announcement period price reaction should be positively (negatively) related to the abnormal return (volume) experienced during the six-month period prior to the announcement date.

### 3.7.3 Hypotheses Based on the Existing Literature

In addition to the hypotheses based on our model, we also test the following hypotheses that arise from the existing literature:

**H.8 Preferential allotments issued by business group-affiliated firms should experience under-reaction compared to stand-alone firms.**

Baek et al. (2006) find that group firms are able to expropriate shareholder wealth by issuing shares at steep discounts in preferential allotments. As noted earlier, business groups in India often engage in preferential allotments. Given the propensity of business groups to transfer resources across companies (see, for example, Rajan et al., 2000) it is likely that preferential allotments by business groups will be viewed less favorably than private placements made by stand-alone firms. This prediction is also consistent with the Entrenchment Hypothesis.

The detailed hypotheses discussed above can be related to the various theories advanced in the literature relating to the announcement effects of preferential allotments. To summarize, Hypotheses H.1 - H.5 can be classified as the Undervaluation Hypotheses, H.1, (the converse of) H.4, (the converse of H.5) and H.8 as the Monitoring Hypotheses, H.1, (the converse of) H.4, (the converse of H.5) and H.8 as the Certification Hypotheses, (the converse of) H.1, (the converse of) H.4 and H.8 as the Entrenchment Hypotheses, and H.6 and H.7 as the Manipulation Revelation Hypotheses.

### 4 Empirical Analysis

In this section, we present our empirical tests of the hypotheses developed in the previous subsection. First, we discuss the construction of the data sample. Then, we provide details of the empirical methodology used to determine the abnormal return and volume measures that are in turn used to test the hypotheses. Finally, we present summary statistics that describe the data and results associated with our tests.
4.1 Construction of the Database

We obtained data from several sources to build our database of preferential allotments of equity in India. We started with news reports from Bloomberg regarding the announcement dates of preferential allotments of equity. These were matched with corresponding data obtained from the corporate announcements site of the Bombay Stock Exchange (BSE). Once the firms had been identified, the details of the preferential allotments (available as .pdf files) were obtained by searching for each individual firm in the corporate actions dataset on the BSE website. We manually digitized the available .pdf files, extracting data on issue price, names of buyers, types of buyers, purpose of issuing preferential shares, number of shares issued to each subscriber, and proportion of shares issued to the total share capital of the firm. Using this procedure, we were able to obtain a sample of 175 preferential allotments made by BSE-listed firms during the period 2001-2009. In addition, we obtained firm-level financial, ownership, and stock price data from the Prowess database of the Center for Monitoring Indian Economy (CMIE). These data were matched with the data on preferential allotments. After the completion of the matching exercise, our final sample had been reduced to 164 preferential allotments, due to the unavailability of firm-level data for some firms.

The definitions used for identifying family business group-affiliated firms and stand-alone firms, as well as the industry classifications of the firms in the sample, were also obtained from Prowess. (The Prowess industry classification is similar to the three-digit SIC code in the U.S.) Our sample of preferential allotments is spread across 42 industries, with no significant concentration in any one industry. However, software, infrastructure and banking firms each account for more than 5% of the total number of issues.

4.2 Measurement of Abnormal Returns and Abnormal Volume

In order to test the hypotheses related to manipulation, we compute the Cumulative Abnormal Return (CAR) and the Cumulative Abnormal Volume (CAV) over the period prior to the announcement date. Announcement period reactions are estimated by calculating these values around the announcement date. We use the standard single-factor market model to measure the abnormal return on a stock around the announcement date of the preferential allotment. The model is specified as follows:

\[ R_{i,t} = a_i + b_i R_{m,t} + \varepsilon_{i,t}, \]

where \( R_{i,t} \) is the return to security \( i \) at time \( t \), \( R_{m,t} \) is the corresponding market return, \( b_i \) is the sensitivity parameter estimate for security \( i \), \( a_i \) is the intercept term for security \( i \) and \( \varepsilon_{i,t} \) is the
error term. Abnormal return is defined as the estimated error term for a particular security for a given time.

Given that the announcement day of the offer is defined as day 0 in the event window period, abnormal returns are calculated over event window periods of [-1, +1], [-5, +5] and [-10, +10] trading days around the announcement day of the issue. The estimation period used to calculate the parameters in Equation 5 comprises returns over days -240 to -31 prior to the announcement day of the issue. The cumulative abnormal return (CAR) of stock \( i \) for the [-10, +10] window can be defined as follows (the CARs for the other windows are defined similarly):

\[
CAR_{it} = \sum_{t=-10}^{+10} AR_{i,nt} \quad (6)
\]

The cumulative abnormal volume (CAV) is estimated using a model akin to the market model, where the daily volume of a security is regressed on the corresponding day’s market volume.\(^{24}\) We measure market volume as the value-weighted trading volume of the top 1,000 BSE-listed securities:

\[
V_{i,t} = c_i + d_i V_{m,t} + \nu_{i,t}, \quad (7)
\]

where \( V_{i,t} \) is the actual volume for security \( i \) on day \( t \) and \( V_{m,t} \) is the market volume. Abnormal volume is defined as the estimated error term for a given time. CAV, which is similar to CAR, is defined as follows:

\[
CAV_{i,t} = \sum_{t=-10}^{+10} AV_{i,t}. \quad (8)
\]

We calculate the CAR and CAV for three specific windows, namely CAV(−22,−32), CAV(−22,−154) and CAV(−22,−250). The numbers for the three windows correspond to the respective days before the announcement date. The first two windows are used to capture abnormal volumes during the two periods used to compute the SEBI-mandated issue price. The third window, CAV(−22, −250), is used to check for robustness.

4.3 Descriptive Statistics

Table I reports the descriptive statistics of the sample data. Our sample consists of 164 preferential allotments, of which 91 were made to insiders (promoters or owner-managers), and 73 to private equity players, as well as to banks and other outsiders. The variables in the data-set

\(^{24}\)The cumulative abnormal volume is commonly used in empirical analyses of manipulation. For example, Sanders and Zdanowicz (1992) use this variable while investigating insider trading in corporate takeovers.
are presented under different categories - firm, issue and investor characteristics, and the size of the insider holdings. Since there were a few outliers at either end of the data, we winsorized one percent of the sample at both the high and the low end for the following variables: illiquidity, volatility, interest coverage, and debt equity ratio. The average firm size is Indian Rupees (INR) 1,956.35 million, the average illiquidity (as measured by the Amihud measure of illiquidity) is 6.18%, the average daily volatility (of stock returns) is 4.01%, the average interest coverage is 6.03, and the average debt equity ratio is 0.93. The issue size, on average, is 60% of the promoter’s equity or about 16% of the outstanding shares. Owner-managers and private equity investors subscribe to the placements in roughly equal measure, at around 45% each, with the balance being subscribed by banks. On average, the owner-managers’ stake prior to the issue is 42.39%.

To gain further insights, we stratify our sample in three ways: (1) group affiliation of the firm, if any, (2) the price path (“high” or “low”), which determines the SEBI-mandated minimum issue price, and (3) the type of investor. Group firms, on average, are significantly (almost three times) larger than stand-alone firms. In addition, the equity of group firms is more liquid in the secondary market, but experiences similar volatility levels to those of stand-alone firms. Group firms are more levered, by a large margin, in terms of their interest coverage, than stand-alone firms. In terms of the debt-equity ratio, however, there is no significant difference between the two groups. We can also see that stand-alone firms rely less on private equity than do group-affiliated firms (35.2% vs. 49.5%). Other than the size and extent of private equity investment, there are no other significant differences in the issue characteristics between group-affiliated and stand-alone firms, since the two categories of firms appear to exhibit large cross-sectional variation on both dimensions. In particular, we find that issue size and the number of shares outstanding are not significantly different between the two groups.

In a similar vein, we divide the sample into issues that are placed after a high price path has been experienced and those that are placed after a low price path. The average weekly price in the two-week period prior to the relevant date is compared with the average weekly price in the six-month period prior to the relevant date.\textsuperscript{25} If the former (latter) is greater, the price path

\textsuperscript{25}The relevant date is itself 30 days (or 22 trading days) prior to the date of the Extraordinary General Meeting (EGM) held to seek shareholder approval of the preferential allotment. This meeting will occur soon after the announcement date, but the exact date of the EGM is not readily available for our sample firms. We, therefore, make the assumption that the EGM date coincides with the announcement date. Thus, the relevant date is assumed to be one month (22 trading days) before the announcement date.
is classified as a “high (low)” price path. Upon classification of the preferential allotments into those that occur after a “high (low)” price path, we find that there is no significant difference in terms of issue characteristics between these two groups, as shown in Table 1. When the data are stratified by the type of investor, that is, owner-managers (promoters) versus outsiders, we find no significant difference between the two groups, except in the interest coverage ratio. The firms in which owner-managers hike their stakes through preferential allotment are, on average, less leveraged than the others.

The above findings are important because some of the hypotheses being tested apply to the sub-sample of issues that are based on group affiliation (Hypothesis H.8), price path dynamics (Hypothesis H.2) or purchaser type (Hypothesis H.9). Overall, the results reported in Table 1 assure us that our empirical tests based on sub-samples are free of any obvious selection bias.

4.4 Announcement Period Returns

Table 2 reports announcement period returns in the form of CARs for three different windows \([\text{CAR}(-1, +1), \text{CAR}(-5, +5)\text{ and }\text{CAR}(-10, +10)]\) around the announcement dates of preferential allotments.\(^{26}\)\(^{27}\) We study these three windows to take into account possible liquidity effects due to thin trading. To the extent that thin trading is an issue, the \text{CAR}(-1,+1) results are less reliable than the \text{CAR}(-5,+5) and the \text{CAR}(-10,+10) results. The table is divided into seven panels; the first one is related to the overall sample, and the other six are based on different classification criteria. The objective of this classification is to examine whether, at the univariate level, there are any significant differences in the announcement period returns across different groups based on Hypotheses H.1-H.5 and H.8-H.9.

Table 2, Panel A reports the overall announcement period effects for the total sample of 164 preferential allotment announcements. Consistent with Hypothesis H.1, Panel A reports that the overall announcement period effect for preferential allotments is significantly positive for the 5- and 10-day windows around the announcement date, with the effect for the 1-day window being

\(^{26}\)As a robustness check, we also computed the CARs with alternative definitions of the window length to estimate the slope coefficients in the market model regressions in Equation 5. In addition, we estimated the CARs with an adjustment for the market return only - in effect assuming that all the slope coefficients were one. These alternative estimations yielded qualitatively similar results, which are not reported here in the interest of brevity.

\(^{27}\)We also examined a longer window to study the long-term wealth effects of the announcement \([\text{CAR}(-1, +480)]\) and found, in contrast to Hertzel et al. (2002), that the long-term announcement effects of Indian preferential allotments are also positive. Our results are consistent with Barclay et al. (2007), who argue that positive long-term wealth effects are consistent with the Certification Hypothesis.
only marginally significant. This finding is consistent with other empirical studies on preferential allotments.

We now turn to the announcement effects for various slices of the sample. Panel B and Figure 8 indicate that, while the announcement effects for the low price path are significantly positive, the effects for the high price path are not significantly different from zero. Further, on average, low-price-path issues have significantly higher positive abnormal returns than high-price-path issues in the case of the 10-day window. Both these results are consistent with Hypothesis H.2.

Panel C reports the announcement effect for sub-groups stratified by volatility into those that are below the median and those that are above the median. According to Hypothesis H.3, a higher volatility of returns should imply a greater announcement effect because (i) the market infers more good news from a preferential allotment when the uncertainty about the hidden value (asymmetric information) is high, and (ii) owner-managers follow a more cautious preferential allotment policy when the uncertainty in the value of the assets-in-place is high. The announcement effects for the two sub-groups are significant for the 5- and 10-day windows, but not as clear-cut for the 1-day window. However, we do not find any statistically significant differences between the sub-groups. The evidence at the univariate level seems to be inconsistent with Hypothesis H.3.

Panel D shows the announcement period returns for preferential allotments, where the owner-managers hold a higher (lower) than median ownership stake in the firm prior to the announcement date. We can see that the announcement period returns are positive for each of the two sub-groups, but there is no significant difference between the sub-groups. This univariate result is consistent with Hypothesis H.4. Panel E reports the announcement effect for two sub-groups stratified by leverage, measured by the interest coverage ratio, into those that are below the median and those that are above the median. The interest coverage ratio is a better measure of leverage in our case due to the large variation in debt-equity ratios across the sample for firms in different industries. The announcement effects for the two sub-groups are significant for the 5- and 10-day windows, but not as clear-cut for the 1-day window.

Panel F and Figure 9 report announcement period returns for group-affiliated firms and stand-alone firms. The CARs for the group-affiliated firms are significantly lower than those for stand-alone firms for the 10-day window. The results for the other windows are in the same
direction, but the differences between the two groups are statistically significant only for the $\text{CAR} (-10, +10)$ window. This evidence at the univariate level is consistent with Hypothesis H.8. Finally, Panel G and Figure 10 report announcement period returns based on the type of investor, namely, promoters (controlling owner-managers), banks and private equity firms separately (Hypothesis H.5). The announcement period effect indicates that most of the significant positive news from preferential allotments comes from placements to owner-managers. The announcement effect for private equity investors is significant, but only for the 10-day window. Interestingly, the effect for banks is not significant. These results suggest, however, that there are no significant differences in the announcement effects between the investor types. The univariate results are inconsistent with Hypothesis H.5.

Overall, the univariate findings seem to support some of the hypotheses that follow from our model; however, we require a more robust multivariate regression analysis that controls for other factors before we can draw any meaningful inferences.\footnote{To control for any bias in the estimates due to thin trading we also used a “trade-to-trade” returns approach that is based on multi-period event returns, as proposed by Maynes and Rumsey (1993) to address illiquidity effects. The results based on the thin trade-adjusted market model, although not presented here, are similar to the results based on the conventional market model as reported in Equation 5. It turns out that only four stocks in the sample had any gaps in the data due to non-trading.}

The multivariate regression results are reported in Table 3.\footnote{To be consistent with our theoretical model, we also ran regressions using only those issues that were made exclusively to promoters (owner-managers). The number of such placements in our sample was 91. The results are qualitatively similar to the results reported in Table 3, which use the full sample of 164 preferential allotments (with proper controls).} All regressions use $\text{CAR}(-10, +10)$ as the dependent variable, since this measure will be least affected by possible thin-trading effects. The explanatory variables are arranged by category - firm characteristics, issue characteristics, investor characteristics and owner-manager stake.

The significant intercept term in all regressions confirms the standard result of positive announcement effects of preferential allotments (Hypothesis H.1). This evidence also goes against the Entrenchment Hypothesis, which states that preferential allotments are typically made to acquire passive shareholders and should be accompanied by a negative price reaction. Regressions 2 and 3 test Hypothesis H.2, which states that preferential allotments occurring after a low price path should lead to greater announcement effects. The coefficient on the high price path dummy is significantly negative, indicating that preferential allotments issued after a low price path experience higher abnormal returns. Regarding firm characteristics, the announcement date abnormal returns are inversely related to size, a control. As for volatility, Hypothesis H.3 suggests that higher volatility of returns (either due to greater uncertainty about the assets-in-place
or to a higher degree of information asymmetry about the hidden value) leads to a greater announcement effect. This conjecture is confirmed in all four regressions. In terms of economic significance, the results indicate that, for a one standard deviation change in volatility, the $CAR$ would rise by 0.957%.

The leverage coefficient indicates that, for a one standard deviation change in the interest coverage ratio, the $CAR$ rises by 0.06%. We also find that the coefficient on the group dummy is negative and insignificant in all the regressions. This result does not support Hypothesis H.8 which states that abnormal returns are lower for group firms than for stand-alone firms. This result is inconsistent with the Entrenchment Hypothesis posited in Baek et al. (2006).

Hypothesis H.5, which is based on the model, suggests that the announcement effects associated with preferential allotments to owner-managers should be greater than that of preferential allotments to private equity investors. Regression 3 tests this hypothesis and shows that preferential allotments issued to owner-managers do not experience a clearly higher positive reaction than private equity investors or banks. The signs and magnitudes of the coefficients on the private equity dummy and the banks dummy are in the right direction, but statistically insignificant, i.e., they suggest that there is a rank ordering of announcement period returns, with the highest returns occurring for owner-manager placements and the lowest for bank placements. While the evidence from Regression 3 is weak, the results of Regression 4 support our model. The coefficient on the private equity dummy is negative and significant. Private equity investors are often assumed to have superior information (Certification Hypothesis) or to take an active role in monitoring the firm (Monitoring Hypothesis). These results show that, after accounting for controls, there is no support for Hypothesis H.5, i.e., no support for the Monitoring Hypothesis (Wruck, 1989) or the Certification Hypothesis (Hertzel and Smith, 1993).

Regression 4 is specifically designed to test Hypothesis H.4. Regression 4, in addition to all variables in Regression 3, includes owner-manager’s pre-announcement shareholding. As per Hypothesis 4, there owner-manager’s pre-announcement ownership should be unrelated to announcement day returns. Consistent with this hypothesis, Regression 4 results indicated that the coefficient for owner-manager’s pre-announcement ownership is insignificant. To summarize, the univariate tests confirm Hypothesis H.1, and the multivariate regressions provide evidence

---

30We also used the volatility of market model residuals - an estimate of the idiosyncratic risk - rather than total volatility of returns and obtained similar results.
that appears to be in favor of Hypotheses H.2 and H.3. Hypothesis H.4 is not confirmed in the empirical tests.

4.5 Testing of the Hypotheses related to Manipulation

As we discussed in the theoretical section on manipulation, owner-managers have incentives to manipulate the stock price level in the period prior to the announcement date of a preferential allotment. Such manipulation would be in the self-interest of owner-managers because they would be able to issue shares to themselves at a price lower than the fair market value. This empirical section examines the extent of managerial self-dealing. It is important to note that our empirical tests ought to control for the fact that the manipulation of prices prior to the announcement date can affect the announcement period returns. If the market believes that owner-managers manipulate prices downward prior to announcements of preferential allotments, there will be a positive announcement effect (manipulation revelation effect). On the other hand, as shown in our model, manipulation induces owner-managers to pursue an aggressive preferential allotment policy, which causes a reduction in the announcement effect. The manipulation revelation effect suggests a positive relationship between announcement period returns and manipulation proxies. In contrast, the aggressive preferential allotment policy effect suggests a negative relationship between announcement period returns and manipulation proxies. It is an empirical question as to which of these two effects dominates, which we will examine in this section.

The first manipulation proxy we consider is the illiquidity of the firms’ stock. We argue that the greater the illiquidity, the lower is the cost that owner-managers incur if they invest in manipulating the stock price in the period prior to the announcement of a preferential allotment. Thus, we should see a greater degree of manipulation in more illiquid stocks. We use the Amihud measure of illiquidity [Amihud (2002)]. If the manipulation revelation effect dominates, we should see a positive relationship between announcement period returns and illiquidity. On the other hand, if the model’s predicted aggressive preferential allotment policy effect dominates, we should see a negative relationship between announcement period returns and illiquidity.

To probe the manipulation story more deeply, we also use information contained in the price and volume run up before the announcement period to build proxies for the effects of manipulation. The first proxy under this category is the cumulative abnormal volume (CAV) in the pre-announcement period. If there is price manipulation, it is likely to be accompanied by higher abnormal trading volumes. The second proxy is the cumulative abnormal return (CAR) in the
pre-announcement period, which is possibly a better indicator of manipulation.31

We use two different time windows to define the period prior to the announcement period. As discussed earlier, the SEBI-mandated issue price is based on the maximum of the average price in the two-week period prior to the relevant date and the average price in the six-month period prior to the relevant date. Thus, proxies to assess manipulation should examine these two trading windows prior to the relevant date. The two-week period prior to the relevant date would then be the interval \([-22, -32]\) relative to the announcement date, assuming that two weeks is equivalent to ten trading days. Hence, we define the two windows to be \([-32, -22]\) and \([-154, -22]\).32 The first window captures price manipulation that affects the most recent valuation and the second window captures price manipulation that affects the six-month average price.

The cumulative abnormal volume (\(CAV\)) and cumulative abnormal return (\(CAR\)) are computed for all three windows described above. Panel A of Table 4 reports univariate results of these three windows for \(CAR\) and \(CAV\). We find that \(CAR\) is positive for all the three windows: \(CAR(-22, -32)\) and \(CAR(-22, -250)\) are both statistically significant. If price manipulation were rampant, one would expect to see negative \(CARs\) in the period prior to the announcement date. However, it could also be argued that the \(CARs\) could have been even higher if it was not for price manipulation. In other words, price manipulation does not necessarily imply negative \(CARs\), but could imply lower \(CARs\) than otherwise. One cannot, therefore, rule out manipulation on the basis of positive \(CARs\) in the period prior to the announcement date.33 Panel B reports the correlation between \(CAR\) and \(CAV\). As can be expected, there is some positive correlation between the same variables defined over different windows. However, the correlations are stronger only when there is significant overlap between the periods, i.e., the \([-154, -22]\) and \([-250, -22]\) windows.

Table 5 presents the results associated with the tests of Hypotheses H.6 and H.7. Essentially, these regressions extend the regression analysis of Table 3 by including the proxies of manipula-

---

31 As a robustness check, we also computed an alternative proxy of action-based manipulation, the cumulative abnormal turnover (\(CAT\)), which is defined in a manner similar to \(CAV\) except that the volume is scaled by the number of shares outstanding.

32 We also examined a third window \([-250, 22]\), covering the entire year prior to the announcement date, to check the robustness of our specification, and found that the results were similar; we do not report them here, to conserve space.

33 However, it is always possible that information-based or action-based manipulation is taking place; it is conceivable that such manipulative strategies are not accompanied by abnormal volumes. Thus, a lack of abnormal volume is not sufficient evidence to preclude the occurrence of manipulation.
tion in Regression 3 of that table. Our first test (of Hypothesis H.6) is based on *market illiquidity* as a proxy for manipulation. The more illiquid a stock is, the easier it would be to push the price downward, even with a low trading volume. Hence, the greater the illiquidity, the greater is the ease of effective manipulation. Table 5, Regression 1 (and all the remaining regressions in the table) show that announcement period returns are negatively related to the log of the Amihud measure of illiquidity. This result suggests that the aggressive preferential allotment policy, which reflects information asymmetry issues in our model, dominates the manipulation revelation effect. Overall, this evidence is consistent with the main thesis of our paper that information asymmetry is a key driver of the preferential allotment decision. This result also suggests that, for a one standard deviation change in the metric of illiquidity, the $CAR$ is reduced by 0.11%.

Hypothesis H.7 discusses the key empirical tests related to the proxies for the degree of manipulation based on the prior period’s price and volume. It implies that announcement period returns should be positively related to the prior period’s $CAR$, and negatively related to the prior period’s $CAV$. In direct contrast, the manipulation revelation effect argues exactly the opposite: that announcement period returns should be negatively related to the prior period’s $CAR$ and positively related to the prior period’s $CAV$.

Regressions 2-5 in Table 5 contain the manipulation variables $CAR[-32, -22]$, $CAR[-154, -22]$, $CAV[-32, -22]$, and $CAV[-154, -22]$. These regressions show that the coefficients on the two $CAR$ variables are positive and significant, although the $CAR(-22, -154)$ variable is only marginally so. For instance, to understand the economic significance, the coefficient in Regression 2 implies that, for a one standard deviation change in $CAR(-22, -32)$, the contemporaneous $CAR$ would increase by 2.42%. As with the illiquidity proxy of manipulation, these results are also consistent with the model’s aggressive preferential allotment policy effect rather than the manipulation revelation effect. However, the two $CAV$ variables do not have significant coefficients when added to the regression. One possibility is that manipulation may be based on avenues other than trade-based techniques, e.g., adverse information dissemination.

Interestingly, all the variables that were significantly related to announcement period returns (Table 3) continue to retain their significance in Table 5. These findings assure us that the con-

---

34We do not report results for the [-250, -22] window since, due to the substantial overlap with the (-22, -154) window, they are fairly similar. Also, we do not report the results for the $CAT$ proxies because they are qualitatively similar to the results obtained with the $CAV$ proxies.
The empirical literature on private placements of equity suggests that managerial entrenchment is perhaps an important driver of the private placement decision. One would imagine that entrenchment would be of even greater concern for private placements made to owner-managers. Yet, the popularity of preferential allotments to owner-managers, particularly in emerging markets, suggests that there is more to the story than just managerial self-preservation.

5 Conclusion

The empirical literature on private placements of equity suggests that managerial entrenchment is perhaps an important driver of the private placement decision. One would imagine that entrenchment would be of even greater concern for private placements made to owner-managers. Yet, the popularity of preferential allotments to owner-managers, particularly in emerging markets, suggests that there is more to the story than just managerial self-preservation.
In this paper, we propose an extension of the Myers and Majluf (1984) model to show that the optimal investment-financing decision of firms depends on the interaction between information asymmetry and capital constraints faced by owner-managers. If owner managers face mild capital constraints, we show that preferential allotments to owner-managers can partially resolve, if not eliminate the underinvestment problem. This result seems intuitive - there is no information asymmetry problem when insiders finance the equity issue, and therefore unlikely to be underinvestment. Since owner-managers are critical sources of capital in emerging markets, the benefits of resolving the underinvestment problem may outweigh qualms about managerial self-dealing (in the form of a lower issue price), especially given the buffer provided by the regulatory restrictions on the pricing of preferential allotments. Further, when owner-managers are resource constrained, private equity players can help bridge the gap in funding and help resolve the underinvestment problem (even after accounting for the possibility of rights offerings). These results, taken together, suggest a positive role for private placements in resolving the underinvestment problem, in contrast to the negative implications of managerial entrenchment associated with private placements.

We find empirical evidence supporting our model in a sample of preferential allotments in the Indian market. Our results are robust to the possibility of manipulation and support the Undervaluation Hypothesis, which follows from an application of the Myers and Majluf (1984) model to a market environment that has distinctly different institutional arrangements from those typically found in developed markets. Our model could also be extended to examine the general problem of the optimal regulation of private placements.
Appendix 1: Proofs of Proposition 1 and Extensions

A.1.1 Proof of Proposition 1

Let $N$ denote the number of original shares outstanding, $n$ the number of new shares issued (either in the outside equity issue or in the preferential allotment), $P$ the issue price, $V_0$ ($P_0$) the pre-announcement market value (price per share) of the firm at date $\tau = 0^-$, and $V_{0+}$ ($P_{0+}$) the post-announcement value (price per share) of the firm at date $\tau = 0^+$. Then, $P_0 = \frac{V_0}{N}$ and $P_{0+} = \frac{V_{0+}}{N+n}$, where $n$ new shares are issued at an issue price $P$ to raise the capital ($I$) required to invest in the positive NPV investment opportunity.

The pre-announcement market value of the firm will be given by the sum of the market value of the assets-in-place ($AIP$) and the NPV of the investment opportunity ($IO$), which is equal to $x + \frac{y^2}{2}I$. On this date, the market’s expectation of the hidden value ($HV$) is zero. Since the expected value of the assets-in-place ($AIP$) is equal to $s/2$, it follows that $V_0(s = h) = \frac{h}{2} + \frac{x+y}{2} - I$ and $V_0(s = l) = \frac{l}{2} + \frac{x+y}{2} - I$. In general,

$$P_0(s) = \frac{V_0(s)}{N} = \frac{s + \frac{x+y}{2} - I}{N}, s = l, h$$

[does this need to be numbered A.1?]

A.1.2 Fraction of shares “sold” in an outside equity issue

When $n$ shares are issued at price $P$ to raise a capital of $I$, $n = I/P$, and $f$, the fraction of the firm that has to be “sold”, is given by

$$f(s) = \frac{n}{N+n} = \frac{\frac{I}{P}}{N + \frac{I}{P}} = \frac{I}{NP + I}, s = l, h$$

[renumber as A.2?]

---

34Note that $V_{0+}(s)$ should reflect the market’s expectation of the Hidden hidden Value value ($HV$), conditional on the owner-managers’ investment-financing policy. In equilibrium, it will be shown that owner-managers always invest in the positive NPV project under the conditions stated in Proposition 1. The financing policy of owner-managers is characterized by a cutoff signal value ($t(s)$), such that for all signal values below 0 outside equity (OE) is employed, for all signal values in $(0, t^*(s))$ rights offerings are employed, and for all signal values greater than $t^*(s)$, preferential allotments (OM) are employed. Given that $t(s)$ arises from a uniform distribution over $(-H, H)$, the market’s expectation of the Hidden hidden Value value ($HV$) is equal to $(\text{Prob}(t < 0))(E(t|OE) + (\text{Prob}(0 \leq t < t(s))(E(t|RO) + (\text{Prob}(t \geq t(s)))(E(t|OM)$. This implies that the market expectation of $t$ conditional on the owner-managers’ investment-financing policy is given by: $\frac{1}{2}(-H+0) + \frac{(t(s))(t(s) + (H-t(s))(t(s)+H)}{2H} = 0$. Thus, in either case ($s = h$ or $s = l$), the market’s expectation of the Hidden hidden Value value ($HV$) is equal to zero.
If capital is raised from outsiders (OE), the issue price, \( P \), will be equal to \( P_0 \). In a competitive market, outsiders would be unwilling to pay anything more than \( P_0 \). Since owner-managers would want to issue shares to outsiders at the highest possible price, the issue price will be set at \( P_0 \), and Equation 2 implies that

\[
I^{OE}(s) = \frac{I}{NP_0(s) + I} = \frac{I}{\frac{s}{2} + \frac{x+y}{2}}, s = l, h
\]  

[renumber to A.3?] after using the result in Equation 1. [should this be eqn a.1?]

**A.1.3 Fraction of shares “sold” in a preferential allotment**

On the other hand, if \( n \) shares are issued in a preferential allotment, the issue price is not determined by a competitive process. If \( V_1 \) denotes the market value at time \( \tau = -1 \), the issue price will be constrained by the pricing formula as follows:

\[
P \geq \text{Max}\left[\frac{V_0(s = h)}{N}, \frac{V_0(s = l) + V_1}{2}\right]
\]  

[renumber to A.4?] Equation 4 states that the issue price should be greater than or equal to the higher of the current valuation, \( V_0 \), and the average price in the previous period (from time \( \tau = -1 \) to \( \tau = 0^- \)). Since the owner-managers would prefer to issue shares (to themselves) at the lowest possible price, the inequality in Equation 4 will be binding. Note that \( V_{-1} \) is given as follows (after using the result in Equation 1): [is this Eqn 1 from the main text or eqn A.1?]

\[
V_{-1} = V_0(s = h)\pi(s = h) + V_0(s = l)\pi(s = l)
\]  

\[
= [\frac{h}{2} + \frac{x+y}{2} - I] \left(\frac{1}{2}\right) + [\frac{l}{2} + \frac{x+y}{2} - I] \left(\frac{1}{2}\right)
\]  

\[
= [\frac{h+l}{4} + \frac{x+y}{2} - I]
\]  

(5)

It is easy to see that \( V_0(s = l) < V_{-1} < V_0(s = h) \). When \( s = h \), the average market value over the previous period will be lower than the current valuation. In this case, Equation 4[check numbering] implies that the issue price is equal to \( \frac{V_0(s = h)}{N} = \frac{[\frac{h}{2} + \frac{x+y}{2} - I]}{N} \). Equation 4 implies that

\[
I^{OM}(s = h) = \frac{I}{N[\frac{h}{2} + \frac{x+y}{2} - I]} + I = \frac{I}{\frac{h}{2} + \frac{x+y}{2}}
\]  

If \( s = l \), Equation 4 implies that the issue price will be equal to the average price, which (after
using the result in Equation 5) is given by

\[ P_{\text{avg}} = \frac{V_0^-(s = l) + V_{-1}}{2N} = \left( \frac{1}{2N} \right) \left( \frac{l}{2} + \frac{x + y}{2} - I \right) + \frac{1}{2N} \left( \frac{h + l}{4} + \frac{x + y}{2} - I \right) = \left[ \frac{h + 3l}{8} + \frac{x + y}{2} - I \right] \] (7)

Using this issue price in Equation 2, the fraction of shares issued in a preferential allotment will be given by

\[ f^{OM}(s = l) = \frac{I}{N \left[ \frac{h + 3l}{8} + \frac{x + y}{2} - I \right] + I} = \frac{I}{\frac{h + 3l}{8} + \frac{x + y}{2}} \] (8)

In general, the fraction of shares “sold” in a preferential allotment is given by

\[ f^{OM}(s) = \frac{I}{\frac{h + 3s}{8} + \frac{x + y}{2}}, \; s = l, h \] (9)

Note further that the SEBI-mandated issue price in a preferential allotment when \( s = l \) is overvalued given the publicly available information. This overvaluation is given by the difference between \( V_{\text{avg}} \) and \( V_0^-(s = l) \). Note that \( V_{\text{avg}} = NP_{\text{avg}} \), where \( P_{\text{avg}} \) follows from Equation 7. Thus the SEBI regulation-s induced additional premium paid by buyers in a preferential allotment is given by

\[ V_{\text{avg}} - V_0^-(s = l) = \left[ \frac{h + 3l}{8} + \frac{x + y}{2} - I \right] - \left[ \frac{l}{2} + \frac{x + y}{2} - I \right] = \frac{(h - l)}{8} \] (10)

### A.1.4 Owner-managers’ investment-financing decision

At date \( \tau = 0^- \), the owner-managers (promoters) observe a private signal \( (t) \) of the hidden value. Let \( W(t, s) \) denote the expectation (as of date \( \tau = 0 \)) of the wealth of the owner-managers (promoters) on the liquidation date \( \tau = +1 \). The Owner-managers have to choose among three alternatives: (i) No issue (UI): no shares are issued if the project is rejected, (ii) Outside Equity (OE): shares are issued to outsiders, and (iii) Preferential Allotment (OM): shares are issued to owner-managers.

**Case A (No Issue: UI)**

The expected wealth of the owner-managers is given by the expected value of the assets-in-place (AIP), the expected hidden value (HV), and the expected cash flows on the investment
opportunity. Since the project is not undertaken, its NPV is irrelevant in this alternative.

\[ W^{UI}(t, s) = \alpha \left( \frac{s}{2} + \frac{t}{2} \right) \]  

(11)

Case B (Outside Equity: OE)
The owner-managers issue a fraction, \( f^{OE} \), to outsiders and their expected wealth is given by the expected value of the assets-in-place (\( AIP \)), the expected hidden value (\( HV \)), and the expected cash flows on the investment opportunity. Once the fraction, \( f^{OE} \), of the firm is “sold”, the original shareholders are left with the fraction, \((1- f^{OE})\), of the firm. The owner-managers are entitled to a fraction \( \alpha \) of this remaining part. It follows that

\[ W^{OE}(t, s) = \alpha \left(1 - f^{OE}(s)\right) \left( \frac{s}{2} + \frac{x + y}{2} + \frac{t}{2} \right) \]  

(12)

Case C (Preferential allotment: OM)
The owner-managers issue a fraction, \( f^{OM}(s) \), to themselves. In return for this additional shareholding in the firm, the owner-managers have to supply the project’s investment capital of \( I \). Their original shareholding (\( \alpha \)) entitles them to a fraction, \( \alpha \left(1 - f^{OM}(s)\right) \), of the total expected cash flows. In addition, they are also entitled to a fraction, \( f^{OM}(s) \), of the firm’s expected cash flows because of the new shares they have issued to themselves in the preferential allotment. Finally, the owner-managers supply the investment capital \( (I) \) and this shows up as a negative cash flow:

\[ W^{OM}(t, s) = \left[ \alpha \left(1 - f^{OM}(s)\right) + f^{OM}(s) \right] \left[ \frac{s}{2} + \frac{x + y}{2} + \frac{t}{2} \right] - I \]  

(13)

Case D (Rights Offering: RO)
The wealth effect of a rights offering (for the owner-managers) is given by

\[ W^{RO}(t, s) = \alpha \left(1 - f^{RO}(s)\right) \left( \frac{s}{2} + \frac{x + y}{2} + \frac{t}{2} \right) + \alpha f^{RO}(s) \left( \frac{s}{2} + \frac{x + y}{2} + \frac{t}{2} \right) - \alpha I. \]  

(14)

The first term represents the value of the residual claim of the owner-managers after the rights offering, the second term represents the owner-managers’ gains from the present holdings obtained from the rights offering, and the third term represents the proportional investment made by the owner-managers in the rights offering. This expression simplifies asto

\[ W^{RO}(t, s) = \alpha \left( \frac{s}{2} + \frac{x + y}{2} + \frac{t}{2} \right) - \alpha I. \]  

(15)
Note that the issue price in the rights offering is irrelevant because the net wealth gain of the owner-managers is independent of $f^{RO}$.

Comparing $W^{RO}(t,s)$ with the wealth effects from the other alternatives ($OE$, $OM$, and $UI$), we can derive the cutoff levels of the signal $t$ that defines the regions where in which one financing alternative is favored over the other. For instance, comparing $W^{RO}(s)$ with $W^{UI}(t,s) = \alpha \left( \frac{x}{2} + \frac{y}{2} \right)$, we get the result that the rights offering is always preferred to the “no investment alternative” (for all signals of $t$) as long as $\frac{1}{2}(x + y) > I$, i.e., so long as the project is a positive NPV project. Note that the intersections of the $W^{OE}(t,s)$, $W^{OM}(t,s)$ and $W^{UI}(t,s)$ lines lie below the $x$-axis and therefore, the critical points are determined by the intersections of the $W^{RO}(t,s)$, line with the $W^{OE}(t,s)$ with and $W^{OM}(t,s)$ lines.

Comparing $W^{RO}(t,s)$ with $W^{OM}(t,s) = [\alpha(1 - f^{OM}(s)) + f^{OM}(s)] \left[ \frac{x}{2} + \frac{x+y}{2} + \frac{h}{2} \right] - I$ yields the result that the preferential allotment alternative, $OM$, dominates the rights offering alternative, $RO$, for all $t > t(s) = \frac{h-s}{4}$. Finally, comparing $W^{RO}(t,s)$ with $W^{OE}(t,s) = \alpha(1 - f^{OE}(s)) \left( \frac{x}{2} + \frac{x+y}{2} + \frac{h}{2} \right)$, we can conclude that the rights offering alternative, $RO$, dominates the outside equity alternative, $OE$, for signals $t > 0$, for positive NPV projects.

Given the above cutoffs for rights offerings compared with the other alternatives, and the cutoffs between the outside equity, preferential allotment and no investment alternatives determined in the original analysis, we can see that outside equity dominates the other alternatives for all $t < 0$, the rights offering dominates the other alternatives for all $t \in (0, \frac{h-s}{4})$, and preferential allotment dominates the other alternatives for all $t > \frac{h-s}{4}$.

A.1.5 Proof of Corollary 1

Corollary 1 (ii) follows upon from differentiating the expression for $\hat{t}(s)$. Given that $t$ is drawn from a uniform distribution over $(-H, H)$, it follows that the expectation of the hidden value ($HV$), conditional on a preferential allotment, is given by $\frac{\hat{t}(s)+H}{4}$. After substituting for $\hat{t}(s)$, we get an explicit expression for the announcement period effect stated in Equation 2.[is this in the main text or the appendix? numbering of appendix equations needs to be changed to make it clear]. Corollary 1(iii) follows immediately upon from the differentiation of the announcement period return.
A.1.6 Manipulation Model

Manipulation in the model is captured by a spurious dip in the price level at \( \tau = 0^- \) by an amount equal to \( w \). This dip in price is assumed to arise because of strategic trading by the owner-managers in the period prior to the announcement date. Thus, prices at \( \tau = 0^- \) would reflect the drop, \( w \), in both the low price \( (s = l) \) and the high price \( (s = h) \) states of the world. The price is given by \( V_0^- (s) = \frac{s}{2} + \frac{x + y}{2} - I - w \). Due to price manipulation, owner-managers will now be able to issue shares to themselves at a lower price. Note that the expressions for Equations 12-13 depend on \( f^{OE} \) and \( f^{OM} \), as stated in Equations 3 and 9, respectively. These quantities change because of the dip in price by the amount \( w \), as shown below.

\[
f^{OE}(s) = \frac{I}{\frac{s}{2} + \frac{x + y}{2} - w} \quad (16)
\]

\[
f^{OM}(s) = \frac{I}{\frac{k + 3s}{8} + \frac{x + y}{2} - w} \quad (17)
\]

With the above modifications in \( f^{OM}(s) \) and \( f^{OE}(s) \), the cutoffs in a world of manipulation are determined in exactly the same way as before, namely, by comparing Equations 11-13 in a pairwise manner. The above equations follow from this comparison.

It should be noted that manipulation prior to the announcement date is best captured by assuming that investments in manipulation are made at \( \tau = -1 \) and the benefits of manipulation are realized at \( \tau = 0^- \) when the price level drops by an amount equal to \( w \). At time \( \tau = -1 \), owner-managers are unaware of the realization of the hidden value \( (t) \), which is revealed at time \( \tau = 0^- \). Ex-ante, at \( \tau = -1 \), owner-managers have to invest in manipulation activities without knowing the realization of \( t \). Ex-post, (at \( \tau = 0^- \)), they would have liked to have set \( w = 0 \) for low realizations of \( t \) (when they would be issuing outside equity) and the maximum feasible value of \( w \) for sufficiently high realizations of \( t \) (when they would be going for a preferential allotment). Given these ex-post incentives, the ex-ante chosen value of \( w = w^* \) would will be some average of these two extreme situations. It can be determined by integrating the benefits of manipulation over all possible realizations of \( t \) and then maximizing the expression with respect to \( w \), as shown in the equation below. The tradeoffs in this optimization exercise are obvious: Choosing a very high value of \( w \) would will hurt owner-managers whenever if they then observe a low realization of the hidden value \( (t) \) because it would will trigger an outside equity issue at a less than favorable price. The low issue price would will then benefit outsiders at the expense of insiders. On the
other hand, choosing a very low value of $w$ could also hurt the owner-managers if insiders they then observed a high realization of $t$ because it this would would trigger a preferential issue. Owner-managers would then end up purchasing shares at higher prices than otherwise (i.e., if they had invested more in manipulation activities). Choosing an intermediate level of $w$ would will balance these tradeoffs (subject to the usual boundary conditions - in this case $w < l$ in order to ensure positive price levels.).

$$W(w) = \max_{[w]} \left\{ \text{Prob}(s = h) \left[ \int_{0}^{H} W^{OE}(t, s = h; w)dt + \int_{0}^{H} W^{OM}(t, s = h; w)dt \right] \\
+ \text{Prob}(s = l) \left[ \int_{-H}^{f_{OE-OM}(s=l)} W^{OE}(t, s = l; w)dt + \int_{f_{OE-OM}(s=l)}^{H} W^{OM}(t, s = l; w)dt \right] \right\}$$

(18)

A.1.7 Information Asymmetry asymmetry in both Assetsassets-in-place and Investment investment Opportunityopportunity

We now consider the standard Myers and Majluf (1984) setup where information asymmetry applies to both the assets-in-place a well as and the new project. Let the hidden value associated with the NPV of the project be $q$, which is drawn from a distribution with an expected value of 0. We assume that the manager will invest only in positive NPV projects. Equation 11 stays unchanged, but Equations 12 and 13 get are modiﬁed to the equations below:

$$W^{OE}(t, s) = \alpha(1 - f^{OE}(s)) \left[ \frac{s}{2} + \frac{x + y}{2} + \frac{t + q}{2} \right]$$

(19)

$$W^{OM}(t, s) = \left[ \alpha(1 - f^{OM}(s)) + f^{OM}(s) \right] \left[ \frac{s}{2} + \frac{x + y}{2} + \frac{t + q}{2} \right] - I$$

(20)

Now, comparing Equation 19 with Equation 11 yields the following inequality, which has to be satisfied in order for the owner-managers to prefer an outside equity ﬁnancing choice ($OE$) to the underinvestment choice ($UI$):

$$q > \frac{f^{OE}(s)}{1 - f^{OE}(s)}t + \left[ \frac{f^{OE}(s)}{1 - f^{OE}(s)}s - (x + y) \right]$$

(21)

Note that the right hand side is a linear function of $t$ with a positive slope and a negative intercept term, as shown in the figure below. This linear boundary defines the regions of $(q, t)$.
where the owner-managers prefer going for an outside equity issue (OE) rather than under-investing in the project (UI) and vice versa.

Comparing Equation 11 with Equation 20, we can solve for the boundary that defines the regions of \((q, t)\) where in which the owner-managers prefer the preferential allotment choice (OM) to the underinvestment choice (UI). The boundary is given by

\[
q > \frac{1}{\alpha + f_{OM}(s)(1-\alpha)} \left( -f_{OM}(s)(1-\alpha)t + \left[ 2I - f_{OM}(s)(1-\alpha)s \right] - (x + y) \right) \tag{22}
\]

Again, the right hand side of Equation 22 is a linear function of \(t\). However, both the slope and the intercept term are negative, as shown in the figure below. In a similar vein, we can compare Equation 19 with Equation 20 to determine the regions of \((q, t)\) where in which the preferential allotment alternative (OM) is preferred to outside equity (OE). It can be shown that the boundary is defined by

\[
q > -t + \left[ \frac{2I}{\alpha(f_{OE}(s) - f_{OM}(s)) + f_{OM}(s) - (s + x + y)} \right] \tag{23}
\]

The right hand side of Inequality 23 is a linear function of \(t\). It has a slope of -1 and an intercept term that is greater than 0 when \(s = l\), but exactly equal to 0, when \(s = h\). We assume, as before, that \(NPV(IO) > \frac{(1-\alpha)h}{s+x+y} \frac{1+s}{s+x+y} \). This ensures that the threshold cutoff values are such that \(\hat{r}_{UI-OM}(s) < \hat{r}_{OE-OM}(s) < \hat{r}_{OE-U1}(s)\). These cutoff values represent the intersection points of the three lines with the \(x\)-axis.

Equations 21, 22 and 23 are mapped in the figure below. It is interesting to note that the three equations have a common intersection point. A little bit of algebra shows that the common intersection point has the coordinates, \(q^* = t^* = 2[I - (x + y)/2]\), which is the negative of twice the NPV of the project.

Now let us consider the RO alternative. We would have three lines defining the dominance regions of RO versus UI, RO versus OM, and RO versus OE. Note that the only line of relevance is the RO versus UI line. This line tells us about (possibly new) regions where in which UI might dominate the other alternatives. The other two lines have no implications for underinvestment. It turns out that the RO versus UI line is parallel to the \(x\)-axis and intersects the OE versus OM, OM versus UI, and OE versus UI lines at the same point, with \(q^* = t^* = -2NPV!\)
The common intersection point will always lie below the dashed line \( q = I - (x + y)/2 \), which defines the lower bound of the information asymmetry on regarding the NPV of the project. (The lower bound ensures that the manager considers only positive NPV projects.) Thus, the underinvestment situation would will arise only in the area spanned by the curved arrow shown in the graph. In this region of \((q,t)\), the manager would prefers the “No Issue” choice to all three alternatives: both the preferential allotment, the rights offering and the outside equity alternatives. As can be seen in the graph, the underinvestment region lies completely in the infeasible range of \((q,t)\). It follows that the manager will always accept all positive NPV projects and there will be no underinvestment in such projects!

**Figure A 1.1: Asymmetry of information and the firm’s financing decision**

This figure shows how the regions of \((q,t)\) – the combinations of information asymmetry about the NPV of the project \((q)\) and the information asymmetry about the assets-in-place \((t)\) - affect the financing decision. The feasible region of \((q,t)\) lies above the dashed line parallel to (and below) the x-axis. The underinvestment region lies in the infeasible range of \((q,t)\). (To generate the graph, we assume, \(x = 6\), \(y = 4\), \(I = 4\), implying that the NPV = 1. Further, we assume that \(H = 5\), \(h = 10\), \(l = 6\), and \(= 0.25\).)

</table>

This table reports the summary statistics relating to 164 firms that issued preferential allotments (private placements) of equity in India during the years 2001-2009. The statistics for the full sample are reported in the first column. The other columns report statistics based on three sets of sub-samples. The first set of sub-samples divides the sample based on whether a firm is affiliated to a business group (Group-Affiliated Firms) or not (Stand-Alone Firms). The second set of sub-samples divides the sample based on whether the issue was made after a low price path or a high price path. High Price Path (Low Price Path) represents the sub-sample of firms for which the average of the high and low daily closing prices in the two-week period prior to the announcement date was higher (lower) than the average of the weekly high and low average price in the six months prior to the announcement date. The third set of sub-samples divides the total sample based on whether the owner-manager subscribed to the issue or not. The statistics for each set of sub-samples are followed by their respective mean differences along with t-values in parentheses. Market cap represents the average market capitalization at the time of the issue. The amount is reported in crore of Indian Rupees. One US dollar is approximately 45 Indian Rupees and one crore is equal to 10 million. Illiquidity is the average ratio of the daily absolute return to Rupee volume for the period from 240 days to 10 days before the announcement date. Volatility is the (non-annualized) standard deviation of daily returns for the period from 240 days to 10 days before the announcement date. Interest coverage ratio is the ratio of earnings before interest and taxes to interest expenses. Debt-equity ratio is the ratio of total borrowing to net worth. All these variables are winsorized at the 1% level. ***, **, and * represent significance at the 1%, 5%, and 10% levels respectively.

This table reports the cumulative average abnormal return (CAR) around the announcement date for 164 private placements that occurred in India during 2001-2009. Abnormal returns are based on the market model (on the BSE100 Index) over the period [-240,-21]. CAR’s are calculated for three windows, namely, [-1, +1], [-5, +5], and [-10, +10]. Panel A presents the statistics for the full sample. Panel B reports the CAR’s based on whether the preferential allotment occurs after a low price path or a high price path. High Price Path (Low Price Path) represents the sub-sample of firms for which the average of the high and low daily closing prices in the two-week period prior to the announcement date is higher (lower) than the average of the weekly high and low average prices in the six months prior to the announcement date. Panel C reports results based on whether volatility, as measured by the standard deviation of daily returns over the period [-240, -10], is above or below the sample median volatility. Panel D reports results based on whether the owner-managers’ ownership prior to the announcement is above or below the sample median ownership level. Likewise, Panel E and F report whether interest coverage ratio and business group (Group-Affiliated Firms) or not (Stand-Alone Firms). Interest coverage ratio is the ratio of earnings before interest and taxes to interest expenses. Panel G reports results based on whether the investor is the owner-manager, or a bank or a private equity firm. Each panel shows the corresponding mean differences along with their t-values. ***, **, and * represent significance at the 1%, 5%, and 10% levels respectively.

</table>

This table reports regression results for 162 private placements in India during 2001-2009. The dependent variable is the cumulative abnormal return for the -10 to +10 days window (CAR [-10, +10]) around the announcement date. Abnormal returns are based on the market model (on the BSE100 Index) over the period [-240, 31]. High price path (Low price path) represents firms for which the average of the high and low daily closing prices in the two-week period prior to the announcement date is higher (lower) than the average of the weekly high and low average prices in the six months prior to the announcement date. Ln(market cap) represents the natural log of the market capitalization of the firm. Group dummy takes the value 1 (0) if the firm is affiliated to an Indian business group (stand-alone firm). Volatility is measured as the standard deviation of daily returns over the period [-240, -10]. Interest coverage ratio is measured as the ratio of earnings before interest and taxes to interest expenses. Issue size to owner-manager’s equity is the ratio of the number of shares issued through preferential allotment divided by the number of owner-manager shares. Issue size to outstanding shares refers to the number of shares issued through preferential allotment to the number of outstanding shares. Instrument type dummy takes the value 1 (0) if the issue is made as plain equity (equity with warrants or convertibles). Private equity dummy takes the value 1 if the investor is a private equity firm, otherwise it is 0. Bank dummy takes the value 1 if the buyer of the equity is a bank, otherwise it is 0. Owner-manager’s equity represents the percentage of equity held by the owner-managers of the firm. Year dummies are for years between 2001 to 2009. Industry dummies are based on three-digit industry codes. ***, **, and * represent significance at the 1%, 5%, and 10% levels, respectively.

This table reports the Cumulative Abnormal Return (CAR) and Cumulative Abnormal Volume (CAV) for a sample that comprises 164 firms that raised equity in India through preferential allotments during 2001-2009. Panel A reports the CAR and CAV for three specific windows before the announcement date of the preferential allotments. In order to calculate the abnormal return, we estimate the expected return using the market model between the 240 and 31 days before the announcement date. We use the BSE100 index as the benchmark for the Indian market return. Abnormal volume is the difference between the actual volume and the expected volume of a given stock. Volume is measured as the number of shares traded on a given day. Expected volume is calculated by regressing the daily stock volume on the daily market volume using four years of daily data starting from day -300 and going backwards. We use the top 1000 stocks of the Bombay Stock Exchange to calculate the daily average market volume. The same procedure is applied, however, for different windows for CAR[-32,-22], CAR[-154,-22], CAR[-250,-22], CAV[-32,-22], CAV[-154,-22] and CAV[-250,-22]. We report the t-values and the median in the next two columns. Panel B reports the correlations of the CAR’s and CAV’s for the three specific windows. ***, **, and * represent significance at the 1%, 5%, and 10% levels respectively.

</table>

This table reports regression results for 162 private placements in India during 2001-2009. The dependent variable is the cumulative abnormal return for the -10 to +10 days window (\(\text{CAR}[-10, +10]\)) around the announcement date. Abnormal returns are based on the market model (on the BSE100 Index) over the period (-240,-21]. High price path (Low price path) represents firms for which the average of the high and low daily closing prices in the two-week period prior to the announcement date is higher (lower) than the average of the weekly high and low average prices in the six months prior to the announcement date. ln(market cap) represents the natural log of the market capitalization of the firm. Group dummy takes the value 1 (0) if the firm is affiliated to an Indian business group (stand-alone firm). Volatility is measured as the standard deviation of daily returns over the period (-240,-10]. Interest coverage ratio is measured as the ratio of earnings before interest and taxes to interest expenses. Issue size to owner-manager’s equity is the ratio of the number of shares issued through preferential allotment divided by the number of owner-manager shares. Issue size to outstanding shares refers to the number of shares issued through preferential allotment to the number of outstanding shares. Instrument type dummy takes the value 1 (0) if the issue is made as plain equity (equity with warrants or convertibles). Private equity dummy takes the value 1 if the investor is a private equity firm, and 0 otherwise. Bank dummy takes the value 1 if the buyer of the equity is a bank, and 0 otherwise. Owner-manager’s equity represents the percentage of equity held by the owner-managers of the firm. Ln(illiquidity) is the natural logarithm value of the average ratio of daily absolute return to Rupee volume over the period (-240,-10]. CAR[-32,-22],CAR[-154,-22], CAV[-32,-22], and CAV[-22,-154] are the cumulative abnormal returns and cumulative abnormal volumes for the two-week and six-month windows prior to the announcement date. Year dummies are for the years between 2001 to 2009. Industry dummies are based on three-digit industry codes. ***, **, and * represent significance at the 1%, 5%, and 10% levels, respectively.
Figure 8: Cumulative average abnormal returns (CAARs) based on price path dynamics. The sample comprises 164 firms that raised equity through preferential allotment during 2001-2009. In order to calculate the abnormal return, we estimate the expected return using the market model from -240 to -31 days before the announcement date. We use the BSE100 index as the benchmark for the Indian market return. The figure reports the number of days before and after the announcement date on the x-axis and the percentage of cumulative average abnormal return (CAAR) on the y-axis. The figure has two graphs to represent CAARs for “low” versus “high” issue prices. “High” Price (“Low” Price) refers to those firms for which the last two weeks’ average of the high and low prices daily closing prices was higher (lower) than the last six months’ weekly high and low average price.

Figure 9: Cumulative average abnormal returns (CAARs) based on firm affiliation. The sample comprises 164 firms that raised equity through preferential allotment during 2001-2009. In order to calculate the abnormal return, we estimate the expected return using the market model from -240 to -31 days before the announcement date. We use the BSE100 index as the benchmark for the Indian market return. The figure reports the number of days before and after the announcement date on the x-axis and the percentage of cumulative average abnormal return (CAAR) on the y-axis. The figure has three graphs to represent CAARs for preferential allotments made to all firms, group-affiliated firms (Indian business groups) and stand-alone firms.
Figure 10: Cumulative average abnormal returns (CAARs) based on purchaser type. The sample comprises 164 firms that raised equity through preferential allotment during 2001-2009. In order to calculate the abnormal return, we estimate the expected return using the market model from -240 to -31 days before the announcement date. We use the BSE100 index as the benchmark for the Indian market return. The figure reports the number of days before and after the announcement date on the x-axis and the percentage of cumulative average abnormal return (CAAR) on the y-axis. The figure has three graphs to represent CAARs for three types of buyers of preferential equity, namely, promoters, banks and private equity firms respectively.
